The mitotic spindle is crucial to achieve segregation of sister chromatids. To identify new mitotic spindle assembly regulators, we isolated 855 microtubule-associated proteins (MAPs) from Drosophila melanogaster mitotic or interphasic embryos. Using RNAi, we screened 96 poorly characterized genes in the Drosophila central nervous system to establish their possible role during spindle assembly. We found that Ensconsin/Map7 mutant neuroblasts display shorter metaphase spindles, a defect caused by a reduced microtubule polymerization rate and enhanced by centrosome ablation. In agreement with a direct effect in regulating spindle length, Ensconsin overexpression triggered an increase in spindle length in S2 cells, whereas purified Ensconsin stimulated microtubule polymerization in vitro. Interestingly, ens-c null mutant flies also display defective centrosome separation and positioning during interphase, a phenotype also detected in kinesin-1 mutants. Collectively, our results suggest that Ensconsin cooperates with its binding partner Kinesin-1 during interphase to trigger centrosome separation. In addition, Ensconsin promotes microtubule polymerization during mitosis to control spindle length independent of Kinesin-1.

Introduction

During mitosis, the mitotic spindle plays a crucial role in ensuring the correct segregation of chromosomes. One of the principal challenges faced by the cell during mitosis is the assembly of a powerful microtubule (Mt)-based machine mediating the efficient segregation of sister chromatids within a few minutes. Because of their role in defining the plane of cell division, mitotic Mts are also essential for brain homeostasis, a process linked to asymmetric stem cell division (Causinus and Gonzalez, 2005; Wodarz and Nähke, 2007; Neumüller and Knoblich, 2009). The assembly of the spindle is complex and tightly regulated. The association of Mt-associated proteins (MAPs) with Mts and their subsequent dissociation play an essential role in mitotic spindle assembly. Mitotic spindle assembly and chromosome segregation thus require the complex spatial and temporal regulation of MAPs (Gadde and Heald, 2004).

Many MAPs have been identified in various model organisms. These proteins can be classified into two main categories: motor and nonmotor proteins. Through their direct effects on Mt dynamics, Mt sliding, and cross-linking, these MAPs are involved in several steps in mitosis: centrosome separation and positioning, the attachment of Mts to kinetochores (Kts), bipolar spindle formation, chromosome motion, and cytokinesis (Walczak and Heald, 2008). Mt polymerization is promoted by MAPs, such as TOGp/MAP215/msps (Cullen et al., 1999; Tournebize et al., 2000; Cassimeris and Morabito, 2004), and Mts are organized into a fusiform structure by motor proteins (Suwan et al., 1992; Wittmann et al., 1998; Goshima et al., 2005). Spindle size is controlled by the coordinated regulation of Mt end-binding proteins, such as CLASPs, depolymerizing...
kinesins, and the Mt minus end protein known as patronin (Gaetzi and Kapoor, 2004; Maiato et al., 2004, 2005; Laycock et al., 2006; Goodwin and Vale, 2010).

This study focuses on Ensconsin/Map7. We demonstrate, for the first time, the occurrence in Drosophila melanogaster neuroblasts (Nbs) of Ensconsin/Map7-dependent interphase centrosome separation and spindle assembly pathways during mitosis.

Results and discussion

Ensconsin is a general MAP required for mitotic spindle assembly in the fly central nervous system (CNS)

We analyzed the Drosophila Mt interactome from 0–2-h-old embryos, which are characterized by rapid, synchronous cell divisions (mitotic embryos), with the goal of identifying new spindle assembly proteins. In parallel, we also investigated the Mt interactomes of older embryos (2–17 h old), in which most MtS have nonmitotic functions. Mt polymerization was induced by incubation with taxol, and the MAPs and MtS were harvested by centrifugation and resolved by SDS-PAGE (Fig. S1, A and B). We applied a high-throughput proteomics approach, leading to the high-confidence identification of 855 proteins in both samples (Fig. S1, C–E; and Table S2). Using spectral count, a semiquantitative measurement of protein abundance, we classified all the proteins identified as mitotic, general, or interphase MAPs on the basis of their enrichment profiles (Materials and methods).

We investigated the possible role in spindle assembly in vivo of 96 poorly characterized genes by applying RNAi to the fly CNS (Table S3 and Fig. S1 F; Dietzl et al., 2007; Mummery-Widmer et al., 2009; Neumüller et al., 2011). The new putative mitotic genes identified by this approach (Fig. S1 G and Table S1) included Ensconsin (CG14998). We used ensc mutants to investigate the role of this gene in mitotic spindle assembly (Fig. 1 B, bottom). We used three known Ensconsin mutant alleles: enscΔC (C-terminal deletion), enscΔN (N-terminal deletion), and enscΔNull (full deletion, hereafter referred to as ensc; Sung et al., 2008). Western blot analyses showed all three mutant strains to have similar low levels of Ensconsin protein (see Fig. S3 A).

Ensc mutants had small brain lobes (Fig. 1 A) and a higher mitotic index (1.2 ± 0.5% in wild-type [WT] brains and 2.6 ± 1.0% in ensc mutant brains; n > 3,000 cells, 6 brains), which suggests that ensc mutation caused a mitotic delay due to prolonged spindle assembly checkpoint (SAC) activation. We tested this hypothesis with the double knockdown of Ensconsin and the SAC protein Mad2 by RNAi, with confirmation of the depletion of the protein (Fig. S2 A). Kt/Mt attachment defects were revealed by the large numbers of lagging chromatids during anaphase in double RNAi (6/30 anaphases) but not in cells subjected to mad2 or ensc RNAi (n > 40 anaphases; Fig. S2, B and C). In addition, flies producing double-stranded RNAs (dsRNAs) for either Ensconsin or Mad2 were viable, whereas flies producing both these RNAs died. This indicates that the SAC is required to prolong mitosis and to correct deleterious Kt–Mt attachment.

Ensc and Kinesin-1 mutant Nbs display similar centrosome separation defects during interphase

A close examination of ensc mutant Nb spindles revealed that the centrosomes were not fully separated at prophase (Fig. 1 B, top; n = 20/91) and that metaphase spindles were shorter than WT spindles (Fig. 1 B, bottom; n > 300 spindles).

Time-lapse imaging of dividing Nbs producing a GFP-tagged β-tubulin showed the time between nuclear envelope breakdown (NEBD) and anaphase onset to be 6.1 ± 0.9 min in WT cells and 8.0 ± 1.2 min in ensc mutants, which is consistent with SAC activation (Fig. 1, C and D, top; and Videos 1–3). We also confirmed that mean spindle length was significantly shorter in ensc mutants (8.2 ± 0.7 µm) than in the WT (10.7 ± 0.7; Fig. 1 D, bottom).

In Drosophila Nbs, unlike most cell types, the centrosomes split and start to separate immediately after cytokinesis (Rebollo et al., 2007; Rusan and Peifer, 2007). The daughter centrosome is immobile, retains Mt nucleation activity, and is connected to the apical cortex, whereas the mother centrosome displays weak Mt nucleation and migrates to the opposite side of the cell. The mother centrosome organizes a second aster shortly before mitosis. The daughter centrosome is therefore inherited by the Nb and the mother centrosome is inherited by the ganglion mother cell (GMC; Conduit and Raff, 2010; Januschke et al., 2011). The angle between the Mt asters before NEBD reflects the efficacy of centrosome separation. It was found to be abnormally low in ensc mutants (Fig. 1 E, top; and Fig. 1 F; see also Video 2), for which 14% of Nbs presented mispositioned asters during prophase (Fig. 1 E, bottom; and Video 3). The mother centrosome is not visible (by GFP-tubulin staining methods) before NEBD. We therefore imaged Nbs expressing YFP-labeled centrosomes and GFP-labeled MtS between two consecutive mitoses (Rebollo et al., 2007; Januschke and Gonzalez, 2010). Centrosome splitting after cytokinesis was normal in ensc mutants, but the separation was incomplete, resulting in the apparent separation defect detected before NEBD (Fig. 2 A, interphase; and Videos 4 and 5). We observed no monopolar spindle formation, which suggests that the machinery required to separate centrosomes at NEBD is functional (Tanenbaum and Medema, 2010). However, due to the late timing of separation, when the mother centrosome started to nucleate MtS at NEBD, it was often anchored to the apical cortex in place of the daughter centrosome and was therefore inherited by the Nb (8/25; Fig. 2 A and Video 5, green line).

Ensconsin is a coactivator of Kinesin-1 in interphase. We therefore investigated whether centrosome separation defects could be also detected after a loss of Kinesin-1 function (Sung et al., 2008; Metzger et al., 2012; Barlan et al., 2013). We found centrosome separation defects in khc<sup>27</sup>/khc<sup>27</sup> mutant brains, which lead to a small angle between centrosomes at NEBD but have no effect on spindle assembly (Fig. 2, B–E; and Videos 6 and 7). Centrosome inheritance was randomized and, in 50% of subsequent mitoses, the daughter centrosome ended up in the GMC (Fig. 2 D, bottom). These data demonstrate that early centrosome separation after cytokinesis is a prerequisite for correct centrosome segregation, a process in which Ensconsin and Kinesin-1...
Ensconsin in centrosome and microtubule dynamics

Gallaud et al.

Enconsin in centrosome and microtubule dynamics

appear to be key players. Interestingly, spindle size and mitotic timing were normal in kinesin heavy chain (Khc)-depleted and mutant Nbs, which indicates a dependence of the short spindle phenotype on Ensconsin but not Kinesin-1 (Fig. 2 D).

Ensconsin is required for Mt growth in mitotic Drosophila Nbs

We analyzed the mitotic defects of the ensc mutants in detail by fully depolymerizing mitotic spindles from WT and ensc Nbs by cold treatment and monitoring Mt regrowth at 25°C (Fig. 3 A). In control tests, we observed large centrosomal asters 30 s after the return to 25°C conditions (Fig. 3 B, left, red arrows; n = 19).

We also detected asters around the main chromosome mass and discrete Kt fibers (Fig. 3 B, white arrows). At 90 s, the WT spindles had a normal, bipolar shape (n = 25). The ensc mutant Nbs displayed weak aster formation around the chromosomes and no obvious Kt fibers after 30 s (n > 30; Fig. 3 B, right). After 90 s, only short spindles with weak, disorganized Mt arrays were present (n = 24). Overall, our results suggest that Ensconsin contributes to the polymerization of spindle Mts. For confirmation of this role, we quantified Mt growth directly by tracking EB1-GFP comets at Mt plus ends in WT and ensc Nbs (Fig. 3 C and Video 8). Measurements of Mt dynamic parameters revealed that the mean rate of Mt polymerization was significantly lower...
Figure 2. **Centrosome separation is defective in kinesin-1 and ensC mutant Nbs.** (A) WT (top and Video 4) and ensC mutant (middle, bottom, and Video 5) Nbs expressing YFP-Asl (to label the centrosomes) and GFP-tubulin (to follow the daughter centrosome and Mts) were analyzed by time-lapse video microscopy. The green and blue lines follow the trajectories of the daughter and mother centrosomes, respectively. The two centrosomes did not separate fully in ensC mutants. For this reason, in several cases (8/25, 32%), when the mother centrosome acquired its Mt nucleation potential, it was attached to the apical cortex in place of the daughter centrosome, and was therefore inherited by the Nb rather than the GMC. (B) Prophase and metaphase in control or khc RNAi-treated Nbs (left) and Western blot analyses of Khc (top) and actin (bottom) after khc or control RNAi (right). (C) Prophase and metaphase in WT and khc^{27}/khc^{63} mutant Nbs. In B and C, tubulin is shown in red, aPKC in blue, and phospho-histone H3 Ser10 in green. (D) Duration of mitosis and centrosome positioning in WT and khc^{27}/khc^{63} mutant Nbs expressing Sas4-GFP (yellow) and Cherry-tubulin (gray). Mitosis lasted 7.2 ± 1.2 min in WT (n = 27) and 7.5 ± 1.5 min in khc^{27}/khc^{63} (n = 48) cells. P = 0.652. Spindle length was 10.9 ± 0.8 µm in WT cells and 11.3 ± 1.8 µm in khc^{27}/khc^{63} mutant cells. The daughter centrosome was inherited by the GMC in 24 of the 48 khc^{27}/khc^{63} mutant cells (50%). Time is given in hours:minutes:seconds. In A and D, the green and the red arrows indicate the daughter and mother centrosomes, respectively. The circles indicate the contours of the cells. Bars, 10 µm. (E) Analysis of centrosome separation angle in WT (green) and khc^{27}/khc^{63} (red) Nbs at NEBD.
Ensconsin in centrosome and microtubule dynamics

- Gallaud et al.

In the *ensc* mutant than in WT Nbs (Fig. 3 D), a difference sufficient to account for the short spindles observed in *ensc* mutants.

Spindle shortening and the duration of mitosis in the Nbs of *ensc* mutants are greater in the absence of centrosomes.

Given the large number of short Mts nucleated by the centrosomes in the regrowth assay, we investigated whether the spindle formation defects observed in *ensc* mutants were greater in the absence of centrosomes. We therefore generated *ensc* and *sas-4* double mutant flies, the *sas-4* gene being required for centrosome duplication (Basto et al., 2006), and monitored cell division (Fig. 4). In *sas-4* single mutants (Video 9, left), the spindle formed without centrosomes and mitosis lasted 9.0 ± 1.2 min (Fig. 4, A and C). In *ensc,sas-4* double mutants (Video 9, right), mitosis lasted significantly longer (10.1 ± 1.2 min) and the distribution of Mts was more strongly affected than in the single mutant (Fig. 4, A and C). The spindles were much shorter in the double mutant (6.7 ± 0.6 µm) than in the...

Ensconsin in centrosome and microtubule dynamics

Gallaud et al.

Consistent with the Ensconsin-dependent stimulation of Mt growth during M phase, S2 cells with higher Ensconsin levels formed longer spindles (10.9 ± 2.1 µm, n = 26) than control cells (7.8 ± 1.0 µm, n = 56; Fig. 5, A and B). In a complementary experiment, we assessed the impact of Ensconsin activity on Mt polymerization in vitro, using purified porcine brain tubulin and recombinant Ensconsin (Fig. 5 C) in a turbidity assay, to determine whether this protein could modify the Mt polymerization rate in vitro (Weis et al., 2010; Gaskin, 2011). Ensconsin stimulated Mt polymerization in a dose-dependent manner (Fig. 5 D). This function is entirely consistent with a lower Mt velocity in the deletion mutant and with a longer spindle length in conditions of Ensconsin overexpression.

In conclusion, our study reveals a dual role for Ensconsin. First, during interphase, this protein promotes centrosome separation and positioning through cooperation with its binding partner, Kinesin-1. Second, it stimulates Mt growth during mitosis, independent of Kinesin-1.

Ensconsin is a mitotic spindle-associated protein that stimulates Mt growth in S2 cells and in vitro

We analyzed the distribution of Ensconsin by staining dividing Drosophila embryos with purified antibodies. Ensconsin colocalized with the mitotic apparatus during early development (Fig. S3 B). Furthermore, studies of a functional Drosophila line ubiquitously expressing the GFP-tagged Ensconsin confirmed the colocalization of Ensconsin-GFP with the Mt network and the mitotic spindle during Nb cell division and in early embryos (Fig. S3, C and D; and Video 10).

Figure 5. Ensconsin promotes Mt growth in cells and in vitro. (A) Ensconsin (Ensc) overproduction in mitotic S2 cells led to the formation of longer spindles. Ensconsin-GFP is green (gray in the panels on the right) and Mts are shown in red (gray in the middle panels). Exogenous Ensconsin-GFP is localized on the mitotic spindle during mitosis. Bar, 10 µm. (B) Analysis of mitotic spindle length in WT (n = 56) and Ensconsin-GFP-overexpressing mitotic S2 cells (n = 26). ***, P = 5.1 × 10⁻¹¹. (C) Recombinant Ensconsin purified, separated by SDS-PAGE, and stained with Coomassie blue. (D) Effect of Ensconsin on Mt polymerization in vitro. Purified porcine brain tubulin was mixed with polymerization buffer supplemented with either PBS or PBS containing Ensconsin on ice. Mt polymerization was induced by heating at 35°C. Absorbance at 350 nm was monitored to evaluate the formation of Mt polymers. After 28 min, the samples were shifted to 0°C to estimate protein aggregation. Ensconsin increased the rate of Mt polymerization and the total number of polymers in a dose-dependent manner (red curves), as shown by comparison with buffer alone (black curve).

sas-4Δ2214 (8.5 ± 1.4 µm) and ensc single mutants (8.0 ± 0.6 µm; Fig. 4 B). In parallel, we repeated the Mt regrowth assay (Fig. 4 D). 1 min after the return to 25°C, long Mts were seen in the WT and the sas-4Δ2214 single mutant, but not in the ensc single mutant and the ensc,sas-4Δ2214 double mutant. Bipolar spindle assembly occurred within 3 min in flies lacking either sas-4Δ2214 or ensconsin, but was severely compromised in the double mutant. These results suggest that the centrosome favors spindle assembly when Mt polymerization rates are low in mitotic ensc mutant cells.

We analyzed the distribution of Ensconsin by staining dividing Drosophila embryos with purified antibodies. Ensconsin colocalized with the mitotic apparatus during early development (Fig. S3 B). Furthermore, studies of a functional Drosophila line ubiquitously expressing the GFP-tagged Ensconsin confirmed the colocalization of Ensconsin-GFP with the Mt network and the mitotic spindle during Nb cell division and in early embryos (Fig. S3, C and D; and Video 10).

Consistent with the Ensconsin-dependent stimulation of Mt growth during M phase, S2 cells with higher Ensconsin levels formed longer spindles (10.9 ± 2.1 µm, n = 26) than control cells (7.8 ± 1.0 µm, n = 56; Fig. 5, A and B). In a complementary experiment, we assessed the impact of Ensconsin activity on Mt polymerization in vitro, using purified porcine brain tubulin and recombinant Ensconsin (Fig. 5 C) in a turbidity assay, to determine whether this protein could modify the Mt polymerization rate in vitro (Weis et al., 2010; Gaskin, 2011). Ensconsin stimulated Mt polymerization in a dose-dependent manner (Fig. 5 D). This function is entirely consistent with a lower Mt velocity in the deletion mutant and with a longer spindle length in conditions of Ensconsin overexpression.

In conclusion, our study reveals a dual role for Ensconsin. First, during interphase, this protein promotes centrosome separation and positioning through cooperation with its binding partner, Kinesin-1. Second, it stimulates Mt growth during mitosis, independent of Kinesin-1.

(D) Mt regrowth assay in WT, ensc, sas-4Δ2214, and ensc,sas-4Δ2214 mutant Nbs. 1 and 3 min after the return to 25°C, numerous long Mts were detected in sas-4Δ2214 Nbs. In the ensc,sas-4Δ2214 double mutant, short Mts were found closely opposed to the mitotic chromatin mass. At 5 min, the spindles resembled Mt bundles rather than the bipolar structure seen in sas-4Δ2214 mutants. aPKC is shown in blue, Mts (α-tub) are shown in red (and gray), and phospho-H3 is shown in green. Bar, 10 µm.
Human Ensconsin/MAF15 was first discovered two decades ago, and was described as a MAP that “ensconces” on Mts (Bulinski and Bossler, 1994). The data presented here reveal previously unidentified roles for this known MAP in the regulation of mitotic and interphase Mtbased processes. Further studies are required to determine how a single MAP can contribute to such different activities during the cell cycle.

Materials and methods

Mt co-sedimentation assay

Canton-S fly populations were amplified, maintained, and fed in population cages with fresh yeast on agar plates twice daily for 5 d. We collected 0−2-h-synchronized embryos, a time period corresponding to syncytial division. In parallel, flies were allowed to lay eggs for 15 h and the collected embryos were left for an additional 2 h to allow the last embryos laid to reach the blastula stage. This protocol discriminates between the dividing/mitotic and differentiating/interphase stages. We disrupted 1 g of mitotic and interphase embryos by passage through a French press in a total volume of 2 mL of lysis buffer (LB: 20 mM Hepes, pH 7.4, 1.5 mM KCl, 1 mM MgCl2, 1 mM EDTA, and 0.5% NP-40) supplemented with protease inhibitor and phosphatase inhibitor cocktails, prepared according to the manufacturer’s instructions (Roche). The crude extracts were filtered and centrifuged for 15 min at 15,000 × g. The resulting supernatant (~1.2 mL) was centrifuged at 100,000 × g for 25 min at 4°C to remove insoluble materials. The mitotic and interphase supernatants were precipitated by 1% 100,000 × g centrifugation, were supplemented with 1 mM GTP and 20 µM taxol, and incubated for 20 min at 25°C. The polymerized Ms and MAPs were then recovered by centrifugation for 20 min at 100,000 × g and 25°C on a glycerol cushion (BRB80: 80 mM Pipes, 1 mM EGTA supplemented with 40% glycerol, 1 mM GTP, and 20 µM taxol). The Mt pellets were washed gently twice with BRB80 and suspended in Laemmli sample buffer supplemented with 5% β-mercaptoethanol.

Liquid chromatography/tandem mass spectrometry (LC-MS/MS)

MAPs were resolved by SDS-PAGE in 4−12% BTIS-Tris polyacrylamide gradient gels (Bio-Rad Laboratories). The gel was stained with SYPRO Ruby gel stain according to the manufacturer’s instructions (Bio-Rad Laboratories). A Geliance charge-coupled device (CCD)−based imaging system (PerkinElmer) was used for image acquisition.

The lanes on the SDS-PAGE gel corresponding to mitotic and interphase/differentiating embryo extracts were cut into 20 gel slices per lane with a disposable lane picker (Gel Company). Gel slices were deposited in 96-well plates. A liquid handling station (MassPrep; Waters) was used, with sequencing-grade modified trypsin (Promega) according to the manufacturer’s instructions, for in-gel protein digestion. Peptide extracts were then dried by evaporation in a SpeedVac (Thermo Fisher Scientific).

LCMS/MS experiments were performed with an LTQ linear ion trap mass spectrometer connected to a Thermo Surveyor MS pump and equipped with a nanoelectrospray ion source (all from Thermo Fisher Scientific). The peptides were separated in a 10-cm-long Picofrit BioBasic C18 column with an internal diameter of 0.075 mm (New Objective), with a linear gradient extending from 2 to 50% solvent B (acetonitrile, 0.1%formic acid) over a period of 30 min, at a flow rate of 200 nL/min. Mass spectra were acquired in the data-dependent acquisition mode (Xcalibur software, version 2.0). Each full-scan mass spectrum (m/z 400–2000) was followed by the collisioninduced dissociation of the seven ions giving the most intense signals. The dynamic exclusion function was enabled (35 s of exclusion), and the relative collisional fragmentation energy was set at 35%.

All MS/MS spectra were analyzed with Mascot (version 2.4; Matrix Science), set up to search against a Drosophila Uniref100 protein database (33,950 entries as of November 2012), assuming digestion with trypsin. The fragment and parent ion mass tolerances were 0.5 D and 2.0 D, respectively. The carboxamidomethylation of cysteine was specified as a fixed modification, and the oxidation of methionine and phosphorylation on serine, threonine, and tyrosine were specified as variable modifications. Two missed cleavages were allowed.

Scaffold (version 3.6.2; Proteome Software, Inc.) was used to sum spectral counts, to validate MS/MS-based peptide and protein identifications, and to group peptides into proteins. Peptide identifications were accepted if they could be established with a probability >95%, as specified by the Peptide Prophet algorithm (Neveïvišťskii et al., 2003), and contained at least two identified peptides. Protein probabilities were assigned by the Protein Prophet algorithm (Keller et al., 2002). Proteins that contained similar peptides and could not be differentiated on the basis of MS/MS analysis alone were grouped to satisfy the principles of parsimony. Semiquantitative spectral count analysis results obtained with Scaffold provide an estimate of relative protein abundance between conditions. Enrichment ratios were calculated from spectral count information for interphase extracts.

Functional enrichment analysis and network analysis

We used Cytoscape 2.8.3 and BiNGO version 2.4.4 to identify biological processes overrepresented among the proteins classified into mitotic, general, or interphase MAPs (Shannon et al., 2003; Maere et al., 2005). We used BiNGO with the GO Slim Generic Gene Ontology Annotation. The significance threshold was set at P = 0.05 (hypergeometric test, Benjamini and Hochberg family-wise error rate correction).

Plasmid constructs

All constructs were based on isoform B of Ensconsin, which has been shown to rescue ens mutants (Sung et al., 2008). All cloning procedures were performed with the Gateway system (Life Technologies) and the clones were checked by sequencing. Full-length Ensconsin, the N-terminal Mbdomain domain-human homology domain 1 domain (MBD/EB1), and the conserved C terminus-Erb2 domain were amplified by PCR and inserted into the pENTR/TOPO vector (Life Technologies) to create the entry clones from PCR products: full-length Ensconsin (EnsCFL), with a STOP codon, with the primers 5′-CACCAATAGGGAGAATTTTCGAC-3′ and 5′-CAGCAGGAAATATTTTTCGAC-3′; an N-terminal fragment containing the EB1 domain (EnsC-EB1), with the primer 5′-ACCAATGAGGGAGAATTTTCGAC-3′, and 5′-GGGGGCAAAACAC-3′; and an N-terminal fragment containing the EB1 domain (EnsC-EB2), with the primers 5′-ACCATCGAGGCTGCGCCAAAGAGACCATCAGC-3′ and 5′-CAGCAGGAAATATTTTTCGAC-3′; and a C terminus containing fragment of the C terminus-Erb2 fragment (EnsC-EH2), with the primers 5′-ACCATCGAGGCTGCGCCAAAGAGACCATCAGC-3′ and 5′-CAGCAGGAAATATTTTTCGAC-3′ into pMT/V5-HisTOPO.

Isolform E of EB1 was amplified by PCR with the oligonucleotides 5′-CAGCAGGAAATATTTTTCGAC-3′ and 5′-AACATCGAGGCTGCGCCAAAGAGACCATCAGC-3′ and inserted directly into pMT/V5-HisTOPO.

The open reading frames encoding EB1 and Ensconsin were introduced into pUWG with Gateway technology (Invitrogen) to produce the constructs pUWG-EB1 and pUWG-Ens in use for fly transformation, allowing the ubiquitous expression of GFP-tagged proteins.

Fly strains

Flies were maintained under standard conditions at 25°C. Transgenic flies with the following genotypes were used for RNAi: TubGAL80*,69B-GAL4 and 69B-GAL4. Transgenic flies carrying UAS and hairpin sequences were obtained from the Vienna Drosophila RNAi Center (Dietzl et al., 2007). Flies expressing the full-length EB1-GFP and full-length Ensconsin-GFP constructs were used for time-lapse imaging. They were obtained from BestGene Inc. after P-element-mediated transformation with the pUWG-EB1 and pUWG-Ens vectors. The Ensconsin-GFP transgene conferred early rescue of the viability of ens mutants. Asterless-YFP (Aſ) expressing flies (Rebold et al., 2007) were provided by C. Gonzalez (Institute for Research in Biomedicine, Barcelona, Spain). Khc mutant flies carrying amino-acid substitutions have been described elsewhere (Djagaeva et al., 2012) and were generated by A. Guichet (Institut Jacques Monod, Paris, France), B. Saxon (University of California, Santa Cruz, Santa Cruz, CA), and A. Ephrussi (European Molecular Biology Laboratory, Heidelberg, Germany). A combination of Khc27 (null allele) and Khc23 (hypomorphic allele) was used in this study. The strains expressing mCherry-α-tubulin and GFP-Sas-4 were provided by R. Basto (Institut Curie, Paris, France) and M. Bettencourt-Dias (Instituto Gulbenkian de Ciência, Oeiras, Portugal), respectively. The ensconsin mutant fly stocks ensCΔ (C-terminal deletion), ensCΔN (N-terminal deletion), and ensCΔnull (full gene deletion, referred to as ens) were described in the Results and discussion section, obtained by Pelement excision, and were provided by P. Rorth (Institute of Molecular and Cell Biology, Singapore; Sung et al., 2008). β-tubulin–GFP flies (Inoue et al., 2004) were provided by M. Savoian and D. Glover (University of Cambridge, Cambridge, England, UK). Jasper-GFP and the sax-GFP mutant (Basto et al., 2006) were obtained from the Bloomington Drosophila stock center.
S2 cells were plated on concanavalin A–coated coverslips and incubated off 50 kD) to a final concentration of 30 µM in PBS (EMD Millipore). Ensc-FL was concentrated on Amicon concentrators (molecular weight cutant antibody production (Eurogentec). For in vitro Mt polymerization assays, forms were generally used for the immunization of rabbits for polyclonal purified Ensconsin EHR1 and EHR2 domains present in all Ensconsin iso-

Ni-NTA resin (QIAGEN) and dialyzed overnight against PBS at 4°C. The TUB-GAL80 RNAi in the brain control of the polyubiquitin promoter. expression under the control of its own promoter (Morin et al., 2001), all Stock Center. With the exception of Jupiter-GFP, which is a trap line with malformities (Donaldson et al., 2001). Brain images were acquired and processed with ImageJ software.

Antibodies and Western blotting
The monoclonal YL1/2 rat anti-detyrosinated tubulin antibody (1:200) and the mouse monoclonal and rabbit polyclonal antiphosphorylated histone H3 [Ser10] antibodies (1:50) were obtained from EMD Millipore. The anti-GFP mouse monoclonal antibody (1:1,000) was obtained from Roche, the rabbit anti-PKCδ (C20; 1:200) and rabbit anti-actin (1:4,000) polyclonal antibodies were obtained from Santa Cruz Biotechnology, Inc., the mouse monoclonal anti-V5 antibody was obtained from Life Technologies. For Western blotting, ECL reagent was purchased from Thermo Fisher Scientific.

Live microscopy
Brains expressing the various labeled proteins were dissected in Schneider’s Drosophila medium containing 10% FCS. Isolated brains were loaded and coated on stainless steel slides with fat bodies dissected from WT larvae (Siller et al., 2005). The preparations were sealed with mineral oil (Sigma-Aldrich). Images were acquired with a spinning-disk system mounted on an inverted microscope (Eclipse Ti; Nikon) equipped with a 60x 1.4 NA objective lens at 25°C. Z series were acquired every 60 s with a CCD camera (CoolSNAP HQ2; Photometrics) and a digital camera (iCMOS ORCA Flash 4.0; Hamamatsu Photonics) controlled by MetaMorph acquisition software version X. Images were processed with ImageJ software and are presented as maximum-intensity projections. The basis on their different Mt nucleation potentials after separation, after cytokinesis, or immediately before mitosis (Rebollo et al., 2007). For Mt end tracking in NbS, WT and ensco mutants expressing EB1-GFP were gently squashed in 13.4 µl of fresh Schneider’s media (Invitrogen), between a slide and a 22 x 22-mm coverslip, and the excess medium was absorbed with filter paper. The preparation was sealed with mineral oil 700 (Sigma-Aldrich) to immobilize it and to prevent cell movement during imaging. Mitotic NbS were imaged every 0.5 s for 1 min at 25°C, with a 100x 1.4 NA objective lens.

At least 16 mitotic prometaphase NbS were imaged for comet tracking. The Mt ends were tracked with the single-particle tracking routine available in Icy image analysis software (Olivo-Marín, 2002; Chenouard et al., 2013). The routine parameters were adjusted for the detection and tracking of most of the Mt ends. Nevertheless, because of the high density of MtS, we observed frequent erroneous merging of tracks corresponding to different Mt ends. These errors were filtered out with a customized Matlab (MathWorks) routine. The crude tracks were first broken at track steps characterized by an instantaneous speed of >0.78 µm/s, probably corresponding to erroneous jumps between different Mt tracks. They were also broken at positions at which a change in track direction of >60° was observed. We retained only the remaining filtered tracks corresponding to at least three time points and we estimated the growing speed for each track by averaging the instantaneous speeds along the track.

Cell culture and transfection
S2 cells were transiently transfected as described previously, and protein production was induced by incubation with 0.3 mM CuSO4 for 24 h (Romé et al., 2010).

Mt self-assembly and turbidity assays
A 40 µM solution of tubulin purified from porcine brain was prepared in 1 mM GTP in BR880, and centrifuged for 10 min at 30,000 g, at 4°C, before assembly [Weis et al., 2010]. Tubulin polymerization was induced by incubating the samples at 35°C and was monitored turbidimetrically, at 350 nm, with a UVIKON XS spectrophotometer (BioTek Instruments). We evaluated Ensconsin activity by adding various concentrations of the recombinant protein to tubulin (1.5 or 3.0 µM). For each experiment, the tempera-

ture was shifted to 4°C after 28 min of recording to estimate the degree of protein aggregate formation after assembly [Weis et al., 2010]. Spectrophotometric curves were corrected so as to reflect only Mt polymerization.

Statistical analysis
Differences between datasets were assessed in a nonparametric test (Mann-Whitney-U test), with values of P < 0.01 considered significant.

Online supplemental material
Fig. S1 shows the screening strategy used in this study. Fig. S2 demonstrates that the SAC is required for viability and to prevent chromosome segregation defects after Ens RNAi. Fig. S3 shows the specificity of the Ensconsin antibody and [E1H1] and [E2H2] bound fraction. Table S2 summarizes the phenotypes obtained after RNAi for 18 putative mitotic regulators. Table S2

Ensconsin in centrosomes and microtubule dynamics • Gallaud et al.
shows the proteins associated with mitotic and interphase Mt pellets, respectively, and their relative abundance. Table S3 shows the proteins screened in this study. Video 1 shows WT dividing Nbs. Video 2 shows dividing ensc mutant Nbs with short spindles. Video 3 shows ensc dividing Nbs with centrosome positioning and separation defects. Video 4 shows a WT Nb, expressing labeled centrosomes and Mts, between two consecutive mitoses. Video 5 shows the centrosome separation defects in an ensc mutant during interphase and the defective daughter centrosome inheritance. Video 6 shows the centrosomes and the Mts in a WT Nb. Video 7 demonstrates the defective centrosome separation, positioning, and inheritance defect but normal spindle assembly in hkh mutants. Video 8 shows the Mt dynamics in WT and ensc mutant Nbs. Video 9 shows the short spindle formation in the absence of centrosome and in the absence of both centrosome and Enscincon. Video 10 reveals the Enscincon-GFP fusion protein association with Mts in a dividing Nb and surrounding cells. Suplemental file 1, entitled "trafilat," corresponds to the source code of the routine used to filter the trajectories of the Mt ends obtained from the single particle tracking routine available on the Icy image analysis software. Supplemental file 2, entitled "trafilat", corresponds to the source code of the routine which allows matching the filtering of the Mt end trajectories.
