ACR: Acute cellular rejection
ALP: Alkaline phosphatise
ALT: Alanine aminotransferase
AST: Aspartate aminotransferase
AUC$_{0-12}$: Individual area under the whole blood or intracellular concentration–time curve from 0 to 12 hours
AUC$_{0-12CNA}$: Individual area under the intracellular calcineurin activity curve from 0 to 12 hours
C$_{max}$: Maximal concentration, peak concentration
C$_{12h}$: Trough concentration
EC$_{50}$: Concentration which decreases maximal effect by a half
LC-MS/MS: Liquid chromatography tandem mass spectrometry
PBMC: Peripheral blood mononuclear cells
SEM: Standard error of the mean
SD: Standard deviation
TAC: Tacrolimus
TDM: Therapeutic drug monitoring
WB: Whole blood
Abstract:

Objectives: Despite improvements in patient management and extensive use of therapeutic drug monitoring (TDM), the rate of acute cellular rejection (ACR) remains high in patients treated with tacrolimus (TAC). Moreover, some patients experienced ACR while their whole-blood (WB) concentrations were maintained within the therapeutic range meaning that TDM in WB misrepresents the drug effect. Thus, monitoring TAC directly inside of its effect compartment (intracellular concentrations) or monitoring directly the inhibitory effect on the target protein (calcineurin activity) could be more relevant. The aim of the present study was to explore, in 10 de novo liver transplant recipients, the relationship between TAC whole-blood concentrations, TAC intracellular concentrations and TAC-induced intracellular calcineurin inhibition at day 1 and day 7 after treatment initiation.

Design & Methods: Prospective monocentric observational pharmacokinetic (WB and intracellular concentrations) – pharmacodynamic (calcineurin activity) study.

Results: Full intracellular TAC pharmacokinetic as well as calcineurin activity steady-state profiles are presented in the study. The main result of this study is the lack of relationship between TAC pharmacokinetics (WB and leukocytes) and calcineurin activity in leukocytes at day 1 and day 7 after the graft implantation.

Conclusions: Drug monitoring of TAC intracellular concentrations and determination of the calcineurin activity are among future potential biomarkers of acute rejection in transplant recipients. A better knowledge of the relationship between TAC whole blood and intracellular concentrations and calcineurin activity appears necessary before planning clinical trials to evaluate their potential interest as predictive biomarkers.
Keywords: Immunosuppressive drugs, therapeutic drug monitoring, peripheral blood mononuclear cells, intracellular, calcineurin
1. Introduction:

Tacrolimus (TAC), a calcineurin inhibitor, is widely used to prevent acute cellular rejection (ACR) after liver transplantation [1]. Despite improvements and research efforts in immunosuppression, the rate of ACR remains frequent, varying from 8% up to 30% during the first two years following transplantation [2,3]. Variability in TAC pharmacokinetics might at least partially contribute to liver graft rejection in recipients under TAC. Therapeutic drug monitoring (TDM) based on TAC whole blood concentration assessment is commonly used as a marker to prevent ACR. Besides, a pharmacogenetic approach [4] or a dose individualization based on Bayesian models [5,6] or bottom-up approach [7] may be helpful to further optimize the individualization of TAC dosing in liver transplant recipients. However, it is still uncertain whether these two latter approaches have a significant impact on clinical outcome [8,9]. Finally, some patients continue to experience ACR whereas their TAC whole blood concentrations are within the recommended therapeutic range. Although the mechanism underlying such a phenomenon remains unexplained, this suggests that TAC whole blood concentration does not necessarily correlate with the pharmacological effect of TAC on intralymphocyte calcineurin activity. In this context, measurement of intralymphocyte TAC concentrations and/or a pharmacodynamic approach may be helpful to address this issue.

Assaying intralymphocyte TAC concentrations has been proposed to be of possible interest in evaluating the effects of TAC [10,11]. Indeed, intra- and inter-variability in TAC binding to erythrocytes and lipoproteins can significantly influence the diffusion of TAC in lymphocytes from liver transplant recipients [12], especially during the first
two weeks following the graft implantation. Additionally, efflux-drug transporters such as ABCB1 (P-glycoprotein, P-gp) are expressed on the lymphocytes’ membrane [13]. TAC is known to be a substrate of ABCB1, which counter-transport TAC out of lymphocytes and back into the whole blood compartment. Therefore, the expression level of ABCB1 can impact TAC disposition in lymphocytes [14], especially in the presence of genetic polymorphisms and/or comedication which can cause an increase or decrease in ABCB1 activity on the membrane. Overall, these different factors contribute to the intra-and inter-individual variability in TAC disposition in lymphocytes. In this context, intralymphocyte TAC concentration could be a better surrogate marker than TAC whole blood concentration to reflect the pharmacodynamic effect of TAC.

Finally, calcineurin activity is considered as one of the most relevant pharmacodynamic biomarkers because it directly reflects the pharmacological effect of TAC on its target [15]. Different investigations carried out in liver transplant recipients treated with TAC have shown that calcineurin activity in peripheral blood mononuclear cells (PBMC) was increased before ACR [16–18]. Despite these promising results, the monitoring of calcineurin activity remains difficult in daily clinical practice for analytical and sample preparation reasons [19].

To our best knowledge, no work has attempted to describe the relationship between TAC whole-blood concentrations, TAC intracellular concentrations and TAC-induced intracellular calcineurin inhibition.

In this context, the aim of the present study was to explore this relationship in 10 de novo liver transplant recipients treated with TAC at day 1 and day 7 after graft implantation and investigate if these assays can be conducted on a routine mode.
2. Materials and Methods:

2.1 Patients and data collection:

Ten de novo liver transplant recipients (nine men and one woman) were included in the present study. Seven patients were transplanted because of alcoholic cirrhosis, two patients because of alcoholic and metabolic cirrhosis and one patient because of alcoholic cirrhosis and hepatocellular carcinoma. All patients were involved in the clinical trial "Pharmacogenetic study of tacrolimus in hepatic transplant (CYPTAC'H)" (Clinicaltrials.gov identifier: NCT01388387). Caucasian patients over 18 years of age treated with TAC and who gave their written consent were included in the study. The investigational review board “Comité de Protection des Personnes – Ouest V” approved the study protocol; all patients provided written informed consent and approved the sampling and pharmacokinetic/pharmacodynamic analysis in compliance with the ethical principles of the revised Declaration of Helsinki (2008) and with French regulations. Patients with highly active antiretroviral therapy or with legal guardianship or deprived of freedom were not eligible for the study.

TAC dose, haematocrit, serum protein, albumin, creatinine, total and conjugated bilirubin, AST, ALT and ALP and creatinine clearance were collected or calculated on the day of blood sampling.

Patients were monitored for the first 6 months after transplantation with particular attention given to the occurrence of acute rejection.

2.2 Immunosuppression protocol:

TAC treatment was started either at 8:00 AM or 8:00 PM, depending on the time the surgical procedure was completed. The day of the first administration determined the first day of the study. Patients received initially a dose of 0.04 to 0.05 mg/kg per
12hrs calculated based on the ideal body weight or a dose of 0.02 to 0.03 mg/kg per day. The subsequent doses were adapted to maintain trough TAC whole-blood concentrations between 6 and 10 ng/mL, as recently suggested [20]. From day 1 post-transplantation, patients concomitantly received oral mycophenolate mofetil 1.5 g twice daily and 20 mg of prednisone once daily. They also received a 500 mg methylprednisolone infusion as an induction and one other 500 mg infusion at portal vein clamp removal.

2.3 Blood sampling and cell separation

On their first day of treatment and between the seventh and the tenth day of treatment, each patient underwent complete TAC pharmacokinetics. Five millilitres of peripheral venous blood were collected in EDTA tubes 0, 20, 40, 60, 120, 180, 240, 360, 540 and 720 minutes after the morning oral dose of TAC (Prograf®). Samples were stored at 4°C until cells were separated. According to the literature, blood samples could be stored at 4°C up to 48 hours after the blood collection [21]. Cell separation was achieved using a Unisep U-02 device for density gradient separation of PBMC provided by Novamed© (Jerusalem, Israel) according to previously published procedures [22]. Blood was diluted with RPMI-glutamate (v/v) (Novamed©, Jerusalem, Israel), then centrifuged at 1200 G (without brake) during 20 minutes at room temperature (RT). The cell layer was collected with a pipette, washed twice with RPMI-glutamate and then centrifuged at 250 G during 10 minutes at 4°C. The washing procedure was performed twice. Cell counting was performed on a FC500 (Beckman Coulter, Pasadena, CA, USA) according to previously published works [23,24]. Briefly, 50 μL of cells were incubated with 10 μL of CytoDiff© antibody
cocktail (Beckman Coulter) at RT during 15 min. Then, 500 μL of the “fix-and-lyse”
mix (Versalyse + IOTest3, Beckman Coulter, Pasadena, CA, USA) were added and
the sample was incubated at RT during 15 minutes. Finally, 50 μL of flowcount beads
(Beckman Coulter, Pasadena, CA, USA) were added to calibrate the count.
Because of granulocyte contamination during cell separation, all analyses were
expressed for 1 million white blood cells. High contamination by granulocytes has
already been described in intensive care unit patients with sepsis phase as well as in
autoimmune diseases such as systemic lupus erythematosus [25],[26]. The cell pellet
was then split in aliquots (5x10^5 cells each) dedicated to intracellular TAC
concentration and calcineurin activity assays.

2.4 Assessment of whole blood and intracellular TAC concentrations
TAC was measured in whole blood using a validated liquid chromatography tandem
mass spectrometry (LC-MS/MS) method. The accuracy of our method was ensured
by participation in the Tacrolimus Proficiency Testing Scheme provided by the
Cardiac and Vascular Sciences Analytic Unit of St. George’s Hospital Medical School
(D. Holt, London, United Kingdom).
Intracellular TAC concentration was assayed using a validated LC-MS/MS method
adapted from previously published methods [22,27]. The intra-day coefficients of
variation for TAC controls (50 and 200 pg/million PBMCs) were respectively 8.6 and
9.0%. Coefficients of variation of inter-day analysis of TAC controls (50 and 200
pg/million PBMC) were respectively 2.8 and 8.8%.

2.5 Calcineurin activity assay
Calcineurin activity was determined by using high-performance liquid chromatography with ultra-violet detection as previously described [21]. The peptide used, D-L-D-V-P-I-P-G-R-F-D-R-R-V-S-V-A-A-E, is a partial sequence corresponding to the RII subunit of cAMP-dependent protein kinase. The protein phosphatase 2B (PP2B) substrate was obtained from Bachem (Bubendorf, Switzerland, >98% purity). Briefly, cells were resuspended in 20μl of lysis buffer (1M Tris-HCl, pH 8.0, 1M KCl, Nomidet 40 and tween 20). After a freeze-thaw cycle, lysates were mixed with analysis buffer (50 mM Tris-HCl, pH 7.0, 0.1 M EGTA, 0.5 mM dithiothreitol, 1 mM MnCl₂, 0.3 mg/mL bovine serum albumin, 0.1 mM EGTA, 1 mM CaCl₂, 0.1 μM calmodulin, 500 nM okadaic acid). After sample incubation (15 minutes, 30°C), the reaction was initiated with the addition of phosphorylated peptides. Aliquots (50μl) were sampled at 5 and 10 minutes, and the enzymatic reaction was stopped with 20 μL of perchloric acid 0.5%. A 50 μL aliquot was injected into the chromatographic system. Calcineurin activity was expressed as picomoles of dephosphorylated peptides per minute per 10⁶ cells. The intra-day coefficients of variation for quality control for calcineurin activity (1428 and 2856 pmol) were respectively 1.0 and 2.1%. Accuracy was shown to be good with an average percentage of less than 98.4% (range 96.7–104.5) for the two quality controls. During the validation of analytical method, the method showed a good within-day precision (CV = 13.3%) including all the steps from blood collection to CNA activity assay by using liquid chromatography [21].

2.6 Statistical analysis

The demographic and biological characteristics of the study cohort are presented as mean +/- standard deviation (SD). Creatinine clearance was estimated using the
Modification of Diet in Renal Disease formula [28]. The results of pharmacokinetic and pharmacodynamic data are expressed as mean +/- standard error of the mean (SEM). Individual area under the whole blood or intracellular TAC concentration–time curve from 0 to 12 hours (AUC\textsubscript{0-12}) was calculated according to the trapezoidal formula. This latter was also used to determine AUC\textsubscript{0-12} for calcineurin activity (AUC\textsubscript{0-12CNA}). The ratio TAC intracellular AUC\textsubscript{0-12} over TAC whole-blood AUC\textsubscript{0-12} on day 1 and day 7 was calculated for each patient assuming that mean cell volume was 200 femtoliters [29,30]. Using a mean volume of 200 femtoliters allows us to compare data in blood and within cells on a mass/volume point of view even if it imprecisely reflects the exact volume of the different population cells.

Changes in AUC\textsubscript{0-12CNA} between day 1 and day 7 were also calculated for each patient by dividing the value of AUC\textsubscript{0-12CNA} on day 7 by the value of AUC\textsubscript{0-12CNA} on day 1. Whole blood, intracellular and calcineurin activity AUCs were compared between day 1 and day 7 using a paired Wilcoxon test.

The relationships between TAC whole-blood AUC\textsubscript{0-12}, TAC intracellular AUC\textsubscript{0-12} and AUC\textsubscript{0-12CNA} were tested out using the Spearman correlation test.

All tests were two-sided, and they were considered significant when p-values were < 0.05. Computations were performed using the SAS V9 statistical package (SAS institute, Cary, NC).

3. Results:

3.1 Patients' characteristics

Table 1 presents the baseline demographic and clinical data of the 10 de novo liver transplant recipients included in the study. Biological parameters of patients at day 1 and day 7 after graft implantation are summarized in Table 2.
3.2 TAC blood and intracellular pharmacokinetics

Pharmacokinetic parameters for TAC at day 1 and day 7 after graft implantation are summarized in Table 3. In whole blood, TAC maximum concentration (C_{max}) reached 13.0 ± 9.6 ng/mL at 180 minutes on day 1 and 8.8 ± 5.0 ng/mL at 60 minutes on day 7 (Figure 1). TAC trough concentrations (C_{12h}) were 6.9 ± 3.1 ng/mL and 5.4 ± 3.1 ng/mL on day 1 and day 7 respectively. Corresponding areas under the curve over the administration period (AUC_{0-12}) were 111.8 ± 65.9 ng.h/mL and 81.2 ± 37.2 ng.h/mL, respectively.

For intracellular pharmacokinetics, mean C_{max} reached 116.9 ± 114.7 pg/million leukocytes at 180 minutes on day 1 and 68.3 ± 48.9 pg/million leukocytes at 360 minutes on day 7 (Figure 2). C_{12h} were 71.3 ± 78.5 and 39.5 ± 38.8 pg/million leukocytes at day 1 and 7, respectively. AUC_{0-12} were 909.2 ± 903.7 pg.h/million leukocytes and 673.0 ± 603.0 pg.h/million leukocytes.

The ratio TAC intracellular AUC_{0-12} over TAC whole-blood AUC_{0-12} presented a large variability at day 1 (5.2 to 70, mean 40.3 ± 23.3) and day 7 (8.0 to 114.8, mean 49.3 ± 23.3)

3.3 TAC pharmacodynamics

Figure 3 presents the time course of calcineurin activity in leukocytes at day 1 and day 7 after transplantation. At day 1, calcineurin activity changed in parallel with both whole blood and intracellular TAC concentrations. Thus, the time to achieve the mean maximum calcineurin inhibition (38 ± 16%) was close to that for maximum TAC whole blood and intracellular concentrations. At day 7, the mean calcineurin activity over the dosing interval was unchanged, within +/- 15%.
Mean AUC\(_{0-12CNA}\) at day 1 and day 7 were not statistically different (AUC\(_{0-12CNA}\) = 404.2 ± 251.1 vs 472.8 ± 382.9 pmol/min/10\(^6\) leukocytes, respectively; p=0.95). Overall, mean variation in AUC\(_{0-12CNA}\) between day 1 and day 7 was 1.17 ± 0.65.

### 3.4 PK-PD relationship

A correlation between the whole blood TAC AUC\(_{0-12}\) and the intracellular TAC AUC\(_{0-12}\) was observed at day 1 (rho= 0.69; p = 0.04) but not at day 7 (p = 0.75) (Figure 4). No correlation was found between whole blood TAC AUC\(_{0-12}\) and AUC\(_{0-12CNA}\) at day 1 (p = 0.92) and day 7 (p = 0.10) either between intracellular TAC AUC\(_{0-12}\) and AUC\(_{0-12CNA}\) at day 1 (p = 0.71) and day 7 (p = 0.88) (Figure 5).

No difference could be found between day 1 and day 7 in whole blood AUC\(_{0-12}\) (p = 0.25), intracellular AUC\(_{0-12}\) (p = 0.38), TAC diffusion ratio into leukocytes (p = 1.00), or AUC\(_{0-12CNA}\) (p = 0.74).

### 3.5 Clinical outcome

One patient experienced an ACR during the study. The onset of this acute rejection was 17 days after the surgical procedure. This patient had TAC whole-blood AUC\(_{0-12}\) at day 1 and day 7 (81.3 ng.h/mL and 70.0 ng.h/mL, respectively) close to the mean of the patient study on day 7. In contrast, his intracellular TAC AUC\(_{0-12}\) at day 1 and day 7 (186.2 pg.h/million leukocytes and 112.2 pg.h/million leukocytes, respectively) was approximately 4-fold lower than the mean AUC\(_{0-12}\) of the other patients. He also presented the lowest ratio TAC intracellular AUC\(_{0-12}\) over TAC whole-blood AUC\(_{0-12}\) at day 7 (8.0, study mean 49.3 ± 45.6). Finally, his AUC\(_{0-12CNA}\) significantly increased from 90.7 pmol/min/10\(^6\) leukocytes at day 1 to 189.5 pmol/min/10\(^6\) leukocytes at day 7. The change in AUC\(_{0-12CNA}\) between day 1 and day 7 was 2.09 for this patient.
(mean change for all patients was $1.17 \pm 0.65$), that was the largest increase in the patient study.

4. Discussion:

Different investigations carried out in liver transplant recipients have already investigated the relationship between TAC whole blood concentrations and calcineurin activity in PBMC [16,17,31–33] or between concentrations of TAC in whole blood and PBMC [10,14,34]. To our best knowledge, the present study is the first to study both the pharmacokinetics of TAC in whole blood and leukocytes as well as the TAC-induced effect on calcineurin activity in leukocytes. On the 10 patients included in this study, we did not evidence any relation between TAC pharmacokinetics (whole blood and leukocytes) and calcineurin activity in leukocytes at day 1 and day 7 after the graft implantation.

Capron et al. have recently documented that low TAC concentration in PBMC within the first 7 treatment days was associated with the occurrence of ACR in 90 liver transplant recipients treated with TAC [10]. However, Capron patients were treated with TAC alone whereas our patients received a combination of 3 immunosuppressive drugs. Different investigations have reported that liver transplant recipients experiencing ACR exhibit higher calcineurin activity than those without a rejection episode, suggesting a lower pharmacological impact of TAC [16–18]. This increased calcineurin activity within a graft rejection episode has also been confirmed in patients after lung [35], renal [36] or liver transplantation [18]. The question raised
by these studies is: does a low TAC intracellular concentration leading to an insufficient inhibition of calcineurin activity may result in the development of ACR?

In accordance with Blanchet et al. [31], the present study failed to find any relationship between TAC whole blood pharmacokinetics and calcineurin activity at day 7 after liver graft implantation. Interestingly, we show for the first time that TAC intracellular exposure was not better correlated with calcineurin activity than TAC whole blood exposure. Different reasons can explain this result. Firstly, the interindividual variability in calcineurin activity was very large because of both analytical reasons [37] and aetiology of liver transplantation [32]. Secondly, the profile of calcineurin activity was relatively flat at day 7, probably because our patients were exposed to low TAC whole blood concentrations (mean trough concentration 5.4 ± 3.1 ng/mL). At saturating TAC concentrations, several in vitro studies [38,39] have documented a maximal calcineurin inhibition around 50% for tacrolimus-naïve PBMC. This incomplete inhibition of calcineurin activity is related to a limited FK Binding Protein 12 amount in cytoplasm [39]. The level of expression of other protein, such as FK Binding Protein 13 and FK Binding Protein 25, which binds TAC without inhibiting calcineurin activity, might also contributed to the variability in calcineurin inhibition in PBMCs [40]. In this context, a high intracellular expression of these protein in PBMC could contribute to a lower tacrolimus-induced calcineurin inhibition. In liver transplant recipients, Fukudo et al. estimated an EC$_{50}$ (TAC whole blood concentration which decreases maximal calcineurin activity by a half) of 26.4 ng/mL related to the large diffusion of TAC in erythrocytes [17]. This value of EC$_{50}$ is approximately three-fold higher than the mean TAC whole blood C$_{\text{max}}$ at day 7 observed in the present study, which explains in part the modest calcineurin inhibition observed over the dosing interval in our study. Thirdly, in contrast with day 7, a
significant inhibition of calcineurin activity was observed over the dosing interval at day 1 with a nadir 4 hours after TAC intake which corresponds roughly to the whole-blood and intracellular $C_{\text{max}}$.

The interest of the present study also implemented pharmacokinetic and pharmacodynamic data in liver transplant recipients exposed to low trough TAC whole blood concentrations (target range: 6-10 ng/mL). Indeed, a recent meta-analysis emphasizes the fact that TAC whole blood trough concentrations maintained between 6 and 10 ng/mL in liver transplant recipients during the first month of treatment do not lead to a higher rate of ACR when compared with patients in whom trough concentrations were between 10 and 15 ng/mL [20]. In the present study, baseline calcineurin activity (activity just before the first administration of TAC) and trough calcineurin activity at day 7 were not statistically different (655 ± 401 vs 621 ± 469 pmol/min/10⁶ leukocytes, p=0.11). Additionally, only one patient experienced a histological ACR episode during the 6-month follow-up (Banff score = 4). Although the number of patients included in our study is limited, these results suggest that a lack of significant inhibition of calcineurin activity might not cause acute rejection when immune systems are suppressed by other drugs such as mycophenolic acid and glucocorticoids. Capron et al. have reported a rate of histological ACR around 40% when TAC is used in monotherapy (target blood concentrations of around 6 ng/mL) [10]. This result associated with ours suggests that a low CNA inhibition should be only targeted when TAC is used in combination with other immunosuppressive agents such as mycophenolate mofetil and glucocorticoid. However, given that 80% of our patients were transplanted for alcoholic cirrhosis, the present results are more specific to these patients which frequently exhibited lower
pre-transplantation CNA activity that those observed for other liver aetiologies such as viral cirrhosis, autoimmune liver disease [32]. Further investigations with a larger cohort including non-alcoholic patients are required to address this issue. Also, further pharmacodynamic investigations are necessary to confirm the weak calcineurin inhibition at the target range 6-10 ng/mL and its impact on the incidence of ACR.

Interestingly, the single patient who experienced ACR during the 6-month follow-up exhibited the highest increase in calcineurin activity between day 1 and day 7. Despite a good TAC whole blood exposure, this patient had the lowest TAC exposure in leukocytes at steady-state because of a very low TAC intracellular ratio, which was approximately 6-fold lower than the mean TAC intracellular ratio for the patient cohort. In accordance with the work of Capron et al. [10], this episode of ACR suggests that monitoring TAC concentration in PBMC may be helpful during the first week of treatment to identify patients in whom the TAC intracellular concentration is low and therefore the risk of ACR is high. Although this approach seems easier than the monitoring of calcineurin activity in daily clinical practice, it cannot take account for intracellular factors which can influence calcineurin activity despite a satisfying TAC intracellular exposure. These intracellular factors include among others a low amount of FK Binding Protein 12 and/or a high amount of FK Binding Protein 13 and FK Binding Protein 25 which can bind to TAC without mediating the inhibitory effect of TAC on calcineurin [40]. Therefore, monitoring CNA activity would be more relevant in daily clinical practice; however one limiting factor to its use is the large variability in analytical method related to different factors such as difference in PBMC sample composition and loss CNA activity due to fractionizing and separation
procedures [37]. In this context, the most powerful and useful tool, between intracellular TAC measurement and calcineurin activity monitoring, to identify likely non-responders to TAC therapy has yet to be evaluated.

5. Conclusion:
Drug monitoring of TAC intracellular concentrations and determination of the calcineurin activity are among future potential biomarkers of acute rejection in transplant recipients. A better knowledge of the relationship between TAC whole blood and intracellular concentrations and calcineurin activity appears necessary before planning clinical trials to evaluate their potential interest as predictive biomarkers. The present work highlights new data in liver transplant recipients, in particular complete 12-hour pharmacokinetics of intracellular TAC concentrations as well as complete profiles of calcineurin activity.

Note: C_{max}: maximum concentration over the dosing interval; C_{12h}: concentration measured 12 hours after tacrolimus intake; AUC_{0-12}: AUC over the dosing interval.
Graphical abstract
Highlights:

- The pharmacokinetic-pharmacodynamic relationship of tacrolimus (TAC) is detailed
- The first complete intracellular pharmacokinetics of TAC are shown in this study
- Interest of monitoring intracellular TAC and/or calcineurin activity is suggested
