Abstract—This paper addresses the problem of measuring superdirective Electrically Small Antennas (ESAs) mounted on Printed Circuit Broads (PCBs). Different configurations for connecting the excitation system (SMA connector and coaxial cable) to an array of 31 × 25 mm² integrated in a PCB of 110 × 70 mm² are studied. This configurations are evaluated based on the cable effect on the array’s input reflection coefficient and radiation pattern. Obtained results show that properly connecting the cable with the array mitigates its effect, and hence, it can be measured.

Keywords—Superdirectivity, PCB, current distribution, directivity, cable effect

I. INTRODUCTION

Recent wireless technologies require compact-size antennas. However, Electrically Small Antennas (ESAs) have low efficiencies and omni-directional radiation patterns. Consequently, ESAs are not easy to be measured due to the severe effect of the coaxial cable, even though such a cable may not be present in the final application of the antenna. A poorly balanced antenna can result in common mode currents flowing on the feeding cable surface, which radiates and distorts the true radiation pattern of the Antenna Under-Test (AUT) [1]. There have been many reports about the influence of the coaxial cable on measured characteristics of ESAs (refer to [2] and the references therein). Furthermore, superdirective ESAs add the additional challenge of maintaining the superdirective pattern with the presence of the coaxial cable. This problem was highlighted in multiple works [3-5]. This paper investigates measuring superdirective ESAs mounted on PCBs. Even though, the array with the PCB is not electrically small, simulation and measurement results show that the effect of the excitation system (SMA connector and coaxial cable) can be severe. These results also show that this effect can be minimized and hence, the array can be easily measured.¹

The rest of the paper is organized as follows: section II presents the simulation results. The results are validated via measurements in section III. Finally, section V provides some concluding remarks.

²In order to facilitate the comparison between the different scenarios, the same color-bar scale (0 – 10[Amp/m]) is used for all cases.

³All the simulations are performed using ANSYS HFSS. [6]

1This work was done with the funding of the French National Research Agency as part of the project “SOCRATE” and the support of the “Images et ReSEAUX” cluster of Brittany region, France.

B. Scenario One

In this scenario, the excitation system is directly connected to the array driven element as shown in Figure 3. Due to the excitation proximity to the radiating element the cable radiation affects the array radiation pattern. Hence, the array has equal radiation in both end-fire directions. Figures 11 compares the array input reflection coefficient in this scenario to the reference scenario one. As it can be noticed, the array original resonance frequency of $837 \text{MHz}$ did not change. Figure 4 shows the array directivity radiation patterns. The figure shows that the superdirectivity effect is disturbed and the array maximum total directivity is reduced to $5.7 \text{dBi}$. The figure also shows that the array co-polar directivity is reduced to $5.1 \text{dBi}$ while the cross-polar one is augmented to $1 \text{dBi}$. The HPBW in horizontal and vertical planes are respectively $82^\circ$ and $106^\circ$ and the FBR is equal to $3.2 \text{dBi}$ (Figure 12).

Fig. 3. Antenna geometry with the excitation system in scenario one.

C. Scenario Two

In order to reduce the excitation system effect, the array excitation is extended to the extreme-side of the PCB where a minimal surface current distribution is observed. Figure 5 shows that the current distribution is maximal around the excitation line and the slot between the two ground planes. On the other side, the rest of the ground plane has negligible contribution in the array radiation. Figure 11 shows that the array resonance frequency is shifted to $835 \text{MHz}$ and its matching is lost. This can be attributed to the high coupling between the slot between the two PCB parts and the excitation line, which results in changing the characteristic impedance of the coplanar excitation line. Figure 6 shows that the array superdirective radiation pattern is also lost and the array has a maximum total directivity of $3.7 \text{dBi}$. The figure also shows a comparable co-polar and cross-polar directivity (about $2.5 \text{dBi}$). The HPBW in horizontal and vertical planes are respectively $322^\circ$ and $208^\circ$ and the FBR is equal to $2.1 \text{dBi}$ (Figure 12).

Fig. 6. Simulated 3D directivity radiation pattern in scenario two. (a) Total, (b) co-polar and (c) cross-polar.
D. Scenario Three

In this scenario, the array excitation line is extended to the left-side of the PCB where also a minimal current distribution on the array surface is observed. Figure 7 shows the array geometry in this scenario and the surface current distribution. The Figure shows that the current distribution is approximately the same as in the reference scenario. Consequently, the cable radiation is mitigated and the array both input reflection coefficient and radiation pattern are preserved. Figure 11 shows that the array original resonance frequency of 837 MHz is shifted to 840 MHz. Furthermore, Figure 8 shows that the array is superdirective with a maximum total directivity of 6.8 dBi. The array co-polar directivity is 6.6 dBi while the cross-polar one is −1 dBi. The HPBW in horizontal and vertical planes are 76° and 110° respectively and the FBR is equal to 6.4 dB (Figure 12).

![Fig. 8. Simulated 3D directivity radiation pattern in scenario three. (a) Total, (b) co-polar and (c) cross-polar.](image)

E. Scenario Four

This scenario is similar to the previous one, however, a horizontal the excitation system is connected to the array. Figure 9 shows the array geometry and surface current distribution. The figure also shows that the current distribution is similar to the reference scenario’s one. Hence, as it can be noticed from Figure 10 the array original superdirective radiation pattern is maintained with a maximum total directivity of 6.8 dBi. It can also be noticed that the array co-polar directivity is about 6.8 dBi while the cross-polar one is about −1 dBi. The HPBW in horizontal and vertical planes are respectively 72° and 118° and the FBR is equal to 6.8 dB (Figure 12). Figure 11 shows that the array resonance frequency is shifted to 841 MHz.

III. RESULTS VALIDATION VIA MEASUREMENTS

To validate the simulation results, prototypes of scenarios one, three and four were fabricated and measured. Photographs of the prototypes are given in Figure 13. The measured input reflection coefficient for different scenarios is given in Figure 14. The obtained resonance frequencies are in very
good agreement with simulated ones. A difference less than 2% is noticed for all scenarios. This difference is probably due to the dispersion of the commercial SMD loads. The measured resonances are wider than the simulated ones while the measured resonances are weaker than the simulated ones. This can be due to higher dielectric losses in measurement than simulation. The 3D far-field radiation patterns are measured in SATIMO stargate (SG 32) near-field measurement system and shown in Figure 15. There is a good agreement with the simulation results in the main beam direction. The difference in the backward direction can be attributed to the measuring system and environment. The measured HPBW in horizontal and vertical planes are respectively 84° and 118° for scenario one, 79° and 136° for scenario three and 68° and 89° for scenario four. The maximum total directivity for the three scenarios are respectively 5.6dBi, 5.9dBi and 7.3dBi. Finally, Figure 16 shows the measured 3D total directivity radiation patterns for scenarios one, three and four.

### IV. Conclusion

In this paper, measuring superdirective ESAs integrated in PCBs was investigated. Different scenarios for connecting the excitation system to the antenna were evaluated. The obtained results showed that a proper connection of the excitation system can reduce its negative effects, and hence, the antenna can be measured.
