Abstract

Hemp concrete is a bio-based material which is currently undergoing a growing development. Its hygrothermal behaviour highly depends on the evolution of the moisture content which has a significant influence on heat and moisture transfer. Hysteresis phenomenon and temperature effects on sorption process make difficult the prediction of the moisture content evolution.

Hysteresis phenomenon determines the equilibrium moisture content during successive adsorption / desorption cycles. Temperature influences also the equilibrium moisture content: the warmer the temperature, the lower will be the equilibrium moisture content at the same relative humidity. These two phenomena are most often neglected for modelling the moisture content evolution in heat and moisture transfer models. This can cause significant discrepancies to predict the hygrothermal response of a material subjected to climatic variations.

This paper intends to contribute to the better knowledge of such sorption processes by providing new measurements and by analysing and comparing different theoretical approaches. Some adsorption and desorption main and intermediate scanning curves are measured at two different temperatures. Models taking into account these phenomena are presented. The comparison between experimental and numerical results shows that the theoretical approaches investigated are promising.

Keywords

Bio-based material; Hemp concrete; Hysteresis; Sorption process; Temperature

1. Introduction

In a context of sustainable development, one of the concerns in the building construction sector is the choice of environmentally friendly and healthy materials. In the French climatic conditions, bio-based materials appear as a good solution to address energetic and environmental issues [1]. Different compositions and methods of manufacturing give to hemp

concrete a variety of use: wall, floor and roof. For wall, hemp concrete can be precast, moulded in place or sprayed. Because of low mechanical properties [2], it is mainly used as a filling material supported on a timber frame.

Previous studies on hemp concrete showed its interesting hygrothermal properties as building materials: a low bulk density from 300 to 500 kg.m⁻³, a low thermal conductivity of about 0.1 W.m⁻¹.K⁻¹ and a high vapour permeability of 10⁻¹¹–10⁻¹⁰ kg.m⁻¹. s⁻¹.Pa⁻¹ [3-7]. Its porous, hygroscopic and permeable structure gives high moisture transfer and storage capacities. In [8-9], the high moisture buffer value of hemp concrete confirmed its excellent moisture buffer performance. In practice, the monitoring of an individual French dwelling-house made of 30 cm thick sprayed hemp concrete associated with a timber frame structure [10] and of an experimental hemp-lime building house in England [11] showed its ability to dampen variations of temperature and relative humidity.

Previous works showed the significant influence of moisture content on heat and moisture transfer and storage [7, 12-15]. The derivation of the hygrothermal response to climatic variations of a bio-based material like hemp concrete needs thus a thorough knowledge of the moisture content evolution.

As observed for many hygroscopic materials, a significant hysteresis occurs in the hemp concrete sorption process [5, 13]. For these materials, the equilibrium moisture content depends not only on relative humidity but also on moisture history.

For hemp concrete, the hysteretic phenomenon was experimentally and numerically studied at the reference temperature of 23°C in [13]. In this work, the Huang hysteresis model [16] showed its suitability to numerically predict the hemp concrete hysteretic behaviour. Numerical results in good agreement with experimental ones showed the relevance to consider the hysteresis phenomenon to simulate the transient hygric response of hemp concrete [13-15].

These results were obtained at ambient temperature (about 23 °C) but temperature variations can also affect the evolution of moisture content [17, 18]. The latest experimental research highlights the influence of temperature on moisture content for cement-based materials and ordinary concrete [19-23]. Some experimental investigations were also performed on wood [24, 25]. These studies were mainly focused on a high range of temperatures over 20°C up to 80°C for specific applications (durability, drying process...). Others dealt with organic-based products in a temperature range close to the one encountered in operative building applications between 0°C and 40°C [26-29]. In all studies, the warmer the temperature, the lower the equilibrium moisture content at the same relative humidity was.

In this framework, theoretical and numerical approaches are developed to predict the temperature's effect on moisture content. Three main theories try to explain the influence of temperature on sorption isotherms. The modification of the pore structure due to temperature is one explication. Determination of specific surface areas and mercury intrusion porosimetry tests on cement-based material were performed at different temperatures [30-31]. A temperature increase between ambient temperature and 90°C or 100°C results in a reduction of the specific surface area. The comparison of the pore size distributions shows the presence of pores with larger diameters at 80°C than at 30°C. A modification of the microstructure by an enlargement of pores can thus be attributed to a rise of temperature. This can explain the modification of the sorption isotherms shapes until a temperature of 60°C [32]. Nevertheless, this approach is to be found insufficient to explain the decrease of moisture content at saturation observed in a large range of temperature (between 20°C and 80°C) for cement-based materials [21-23]. To overcome the limitations of the microstructure alteration with the increase of temperature, the modification of the water thermophysical properties with temperature was also investigated together with coarsening of the pore structure [33, 34] or without [35]. Poyet suggested that the microstructure alteration and the water properties

evolution had negligible effects and did not fully explain the results obtained for concrete [21]. He proposed a new approach based on the thermodynamic evolution of sorption mechanism [21]. He based his approach on the exothermic process of adsorption [36] and on the principle of Le Chatelier and the rule of Van't Hoff. According to these principles, increasing temperature promotes the reverse process of adsorption, namely desorption. This approach was validated on cement pastes and concretes [21 37].

Research on temperature effects, on hysteresis effects or on the coupling between temperature and hysteresis are rather scarce in literature. Rode et al. [38] provided some measurements for several building materials (cement paste, spruce, aerated concrete). For the three temperatures investigated (10°C, 25°C and 40°C), no significant differences were observed for aerated concrete both in adsorption and desorption for a range of relative humidity between 10% and 80%. For very high relative humidities over 80% and very low below 10%, more differences are observed between each sorption isotherms. Furthermore, the results obtained by Rode et al. are in accordance with the hypothesis of Ishida [39] which assumes that an increase of temperature results in a reduction of the hysteresis loop.

This paper aims to provide some experimental measures to identify the influence of both temperature and hysteresis on the moisture content evolution in hemp concrete. The range of relative humidity between 20%RH and 85%RH chosen in this paper is supposed to be representative of the variations in France for a hemp concrete wall in typical configuration. Hysteresis phenomenon is modelled using the Huang hysteresis model. The theoretical approach (thermodynamic equilibrium move) used for concretes and cement-based materials is applied in the case of hemp concrete. The performance of the thermodynamic model is compared with experimental results collected on hemp concrete at two different temperatures. This approach is extended to model the influence of both hysteresis and temperature and the results are discussed.

2. Theory

2.1. Sorption isotherm modelling

Different approaches are to be found in literature to model the sorption isotherms. In this paper, two models are chosen and compared: the GAB model based on the physical sorption mechanism [40-44] and the Van Genuchten (VG) model based on the moisture transport [45].

The GAB equation is described by Eq. (1):

$$u_j(RH) = \frac{a_j b_j u_m RH}{(1 - b_j RH)[1 + (a_j - 1)b_j RH]} = \frac{u_{sat} RH(1 - b_j)[1 + (a_j - 1)b_j]}{(1 - b_j RH)[1 + (a_j - 1)b_j RH]} \quad (1)$$

$$j = ads \text{ or } des$$

where u_{ads} [kg/kg] and u_{des} [kg/kg] represent the main adsorption and desorption functions, respectively, RH [%] the relative humidity. u_m [kg/kg] is the molecular moisture content, u_{sat} [kg/kg] is the saturated moisture content, a_j and b_j depend on the molar heat of adsorption and the molar latent heat of vaporization. In practice, parameters are derived to fit experimental data.

The VG model was initially developed to predict the unsaturated hydraulic conductivity in soils and the equation of the model was then adapted for building materials by using relative humidity instead of capillary suction as state variable. It mathematically describes the main adsorption and desorption curves with a single relation given by Eq. (2) :

$$u_j(RH) = u_{sat} \left[\left(1 + \left| \alpha_j \frac{RT}{M_l g} \ln(RH) \right|^{\eta_j} \right)^{-\left(1 - \frac{1}{\eta_j}\right)} \right], j = ads \text{ or } des \quad (2)$$

u_{sat} [kg/kg] is the saturated moisture content. R [8.314 J.mol⁻¹.K⁻¹] is the ideal gas constant, M_l [18 g.mol⁻¹] the molar water mass, g [9.81 m².s⁻¹] the gravity acceleration and T [296.15 K] the reference temperature. Parameters α_j and η_j are calculated by fitting experimental data.

2.2. Hysteresis modelling

Fig. 1 provides a schematic view of a hysteresis loop for a desorption / adsorption cycle.

Fig. 1 Schematic view of main and intermediate scanning curves

According to Huang's model, equations (3) and (4) describe respectively the adsorption and desorption scanning curves after a series of alternating processes of desorption and adsorption:

$$u(RH, i) = u_r(i) + (u_s(i) - u_r(i)) \frac{u_{ads}(RH)}{u_{sat}} \quad (3)$$

$$u(RH, i) = u_r(i) + (u_s(i) - u_r(i)) \frac{u_{des}(RH)}{u_{sat}} \quad (4)$$

i represents the number of switches between adsorption and desorption phases. $u_r(i)$ and $u_s(i)$ represent the residual and the saturated moisture contents, respectively. The calculation of these parameters is based on the perfect closure of the scanning curve at reversal points: scanning curve indexed i includes the last reversal point (RH_i, u_i) and the penultimate reversal point (RH_{i-1}, u_{i-1}) .

2.3. Thermodynamic model

The integration of the Clausius-Clapeyron relation [36] between two equilibrium states (p_{v1}, T_1) and (p_{v2}, T_2) gives the expression of isosteric heat q_{st} involved in a sorption process:

$$q_{st}(u) = \frac{R}{M_l} \frac{T_1 T_2}{T_2 - T_1} \ln \left[\frac{p_v(T_2, u)}{p_v(T_1, u)} \right] \quad (5)$$

$p_v = RH \cdot p_{sat}(T)$ [Pa] is the vapour pressure with p_{sat} [Pa] the saturated vapour pressure and T [K] the temperature. The isosteric heat q_{st} is determined from the experimental data of sorption isotherms at two temperatures T_1 and T_2 and from equation (5).

In this paper, two approaches are presented. The first one proposed by Powers and Brownyard [46] consists in fitting the values of $q_{st}(u)$ thanks to the PB equation:

$$q_{st}(u) = l_v + \frac{a}{(b - u)^c} \quad (6)$$

l_v [J.kg⁻¹] is the latent heat of condensation and a , b and c are the fitting parameters.

The second approach consists in first fitting the two experimental isotherms with a sorption model and then express the function $q_{st}(u)$ according to equation (5) [37]. This approach is thereafter named ThD model.

Whatever the chosen approach, the sorption isotherm at any temperature T is finally defined from a known sorption isotherm $RH(T_{ref}, u)$ (with $T_{ref} = T_1$ or T_2) and as follows:

$$RH(T, u) = RH(T_{ref}, u) \frac{p_{sat}(T_{ref})}{p_{sat}(T)} e^{q_{st}(u) \frac{M_l(T - T_{ref})}{R T_{ref} T}} \quad (7)$$

3. Material and methods

3.1. Composition

The material studied in this paper is a compacted precast hemp concrete manufactured by the French SME Easy Chanvre. The manufacturing process consists in mixing quicklime with water and in adding hydraulic lime and defibered hemp shiv. Fresh hemp concrete is filled into moulds and compacted by vibration to produce hemp concrete blocks. The size of the blocks is 30 cm × 30 cm × 16 cm. Hemp concrete formulation is reported in Table 1. Samples are cut in hemp concrete blocks stored for 2 years in a climatic room at 23°C and 50%RH to

ensure ageing. A total of 12 cubic samples representative of the material ($4.5 \times 4.5 \times 4.5 \text{ cm}^3$) are used.

Hemp shiv	374 kg
Unslaked lime	415 kg
Hydraulic lime	158 kg
Water	207 kg

Table 1 *Hemp concrete formulation*

3.2. Density and porosity

The dry bulk density ρ_0 is defined by:

$$\rho_0 = \frac{m_s}{V} \quad (8)$$

In this relation, m_s [kg] refers to the solid mass and V [m^3] to the total volume. Each sample is oven dried, weighed and measured, giving the mass and the volume. The numerical value provided in the paper corresponds to an average of dry bulk densities calculated from the 12 samples.

The density of solid part ρ_r is determined by Eq. (9) from the mass composition of the hemp concrete and the densities of solid part of its components:

$$\rho_r = \frac{m_s}{V_s} = \frac{m_b + m_{hs}}{\frac{m_b}{\rho_{r,b}} + \frac{m_{hs}}{\rho_{r,hs}}} \quad (9)$$

V_s [m^3] is the volume of solid part of hemp concrete. Subscripts b and hs refer to the binder and hemp shiv, respectively. The densities of each solid part $\rho_{r,b}$ and $\rho_{r,hs}$ are experimentally determined by the pycnometer method in [5]: binder about 2400 kg.m^{-3} and hemp shiv about 1670 kg.m^{-3} .

The total porosity n [%] is the ratio of the pores volume to the total volume and is expressed by the relation:

$$n = \frac{\rho_r - \rho_0}{\rho_r} \quad (10)$$

The open porosity n_0 [%] of porous materials is usually determined by hydrostatic weighting. This experimental method was impossible to implement for the studied hemp concrete: the immersion of the samples caused their decomposition. Chamoin used a hemp concrete with the same mix design but which differed in bulk density because of a higher compaction [5]. The hydrostatic weighting on this hemp concrete gave $n_0 = 68\%$ with $\rho_0 = 450 \text{ kg.m}^{-3}$.

An alternative approach is proposed in this paper to determine the open porosity for the studied hemp concrete. Based on MEB views [9], this approach assumes that the closed pores are the micropores embedded in the binder. This implies that the closed pores / binder volume ratio is constant whatever the compaction of the hemp concrete:

$$\left. \frac{V_{closed\ pores}}{V_b} \right|_{Chamoin} = \left. \frac{V_{closed\ pores}}{V_b} \right|_{studied\ hemp\ concrete} \quad (11)$$

The open porosity is thus deduced from the relation:

$$n_0 = n - \frac{V_{closed\ pores}}{V} \quad (12)$$

The saturated moisture content u_{sat} [kg/kg] is given by the relation:

$$u_{sat} = n_0 \frac{\rho_w}{\rho_0} \quad (13)$$

ρ_w [kg.m⁻³] is the liquid water density.

The mass specific surface S_{GAB} [m².g⁻¹] is determined from the relation:

$$S_{GAB} = S_w N_A \frac{u_m}{M_l} \quad (14)$$

S_w [$\approx 10 \text{ \AA}^2$] represents the surface of one adsorbed water molecule, N_A [$6.02 \cdot 10^{23} \text{ mol}^{-1}$] the Avogadro's number. u_m is determined from the GAB model by fitting the experimental data (Eq.1).

3.3. Sorption isotherms

The glass jar method is applied to determine sorption isotherms and sorption cycles in compliance with the EN ISO 12571 procedure. Two temperatures are investigated: 10°C and the reference temperature of 23°C.

A balance with a resolution of 0.1 mg is used to monitor the samples masses. Equilibrium is reached when the change in a sample mass is less than 0.1% within 24 hours. All samples are first dried under vacuum in silica gel to constant mass.

After conditioning, samples are placed into glass jars above a saturated salt solution. The following salts are used as shown in table 2.

Temperature	Equilibrium relative humidity			
	Potassium acetate	Potassium carbonate	Magnesium nitrate	Potassium bromide
10°C	23%	43%	57%	85%
23°C	23%	43%	53%	81%

Table 2 Salts used in desiccators and their equilibrium relative humidity at 10°C and 23°C

The temperature of 23°C is ensured by a climatic room. The measurements are performed at four relative humidity levels: 23%, 43%, 53% and 81%. The samples are divided into two batches of 6 samples each. Six samples are taken stepwise from dry state to 23%RH and 53%RH to determine main adsorption curve data points. These samples are then taken stepwise from 53%RH to 23%RH and back to 53%RH to determine intermediate scanning

curve data points (primary desorption and secondary adsorption). The other six samples are taken stepwise from dry state to 81%RH to determine main adsorption curve data point. These samples are then taken stepwise from 81%RH to 43%RH and 23%RH and back to 43%RH and 81%RH to determine intermediate scanning curve data points (primary desorption and secondary adsorption).

At 10°C, dry samples masses were the same as those obtained before the test at 23°C (variations less than 0.03%). The temperature of 10°C is obtained in a refrigerator. Because of its regulation system, temperature inside the refrigerator varies by a few degrees. To keep constant the temperature of the samples at 10°C, desiccators are placed in an insulating box made with a 3 cm thick styrodur® polystyrene (Fig 2). Temperatures inside and outside the insulating box are monitored with thermocouples of type K. During the tests, temperature variations inside the box do not exceed $\pm 0.5^\circ\text{C}$. The main adsorption data points were obtained increasing relative humidity from dry state to 23%, 43%, 57% and 85%. Then the primary desorption curve was determined decreasing relative humidity from 85% to 23%.

Fig. 2 *Desiccators in the insulating box*

4. Results and discussion

4.1. Density and porosity

Table 3 presents the physical characteristics of the studied hemp concrete. The physical properties obtained are consistent with the literature data [3, 5, 7, 9]. Hemp concrete is a lightweight concrete in which open porosity accounts for a large part of the total porosity. The pore network consists of pores interconnected to the external surface.

Although the few experimental points at very low relative humidities provide a rough estimation of the specific area, the numerical value is consistent with the data found in literature, between 20 and 60 m².g⁻¹ for hemp concrete [3, 5].

Density of solid part ρ_r	2100 kg.m ⁻³
Dry density ρ_0	396 kg.m ⁻³
Open porosity n_0	72%
Total porosity n	81%
Saturated moisture content u_{sat}	1.805 kg/kg
Specific surface area estimated from the GAB model at 23°C	59 m ² .g ⁻¹

Table 3 *Physical properties of hemp concrete*

4.2. Results at the reference temperature of 23°C

The parameters of VG and GAB equations for the main adsorption curve are derived to fit the experimental data with the least squares method.

The saturated state is difficult or even impossible to achieve for porous bio-based materials (appearance of moulds at very high relative humidities, quick emptying of large pores at saturation). Usually, only experimental data of moisture content between 0% and 97% are known. An original approach, largely developed and validated in [13], is used in this paper.

By using the Huang hysteresis model (HH), the parameters of VG and GAB equations for the

main desorption curve listed in table 4 are derived with the least squares method to fit the experimental data (here 81-43-23%) as a primary desorption curve. Fig. 3 a) and b) provide experimental data, the fitted main adsorption and the primary desorption curve 81-43-23%RH determined from VG and GAB equations, respectively. In these figures, the predicted main desorption curve, primary desorption curve 53-23%RH and secondary adsorption curves 23-43-81%RH and 23-53%RH are also plotted.

Temperature	Model	Parameter	Value
23°C	VG	α_{ads}	0.0319
		η_{ads}	1.8096
		α_{des}	0.0151
		η_{des}	1.4058
	GAB	a_{ads}	25.985
		b_{ads}	0.9950
		a_{des}	26.159
		b_{des}	0.5982
10°C	VG	α_{ads}	0.006956
		η_{ads}	2.0008
	GAB	a_{ads}	7.7810
		b_{ads}	0.9916

Table 4 Parameters of VG and GAB equations for hemp concrete

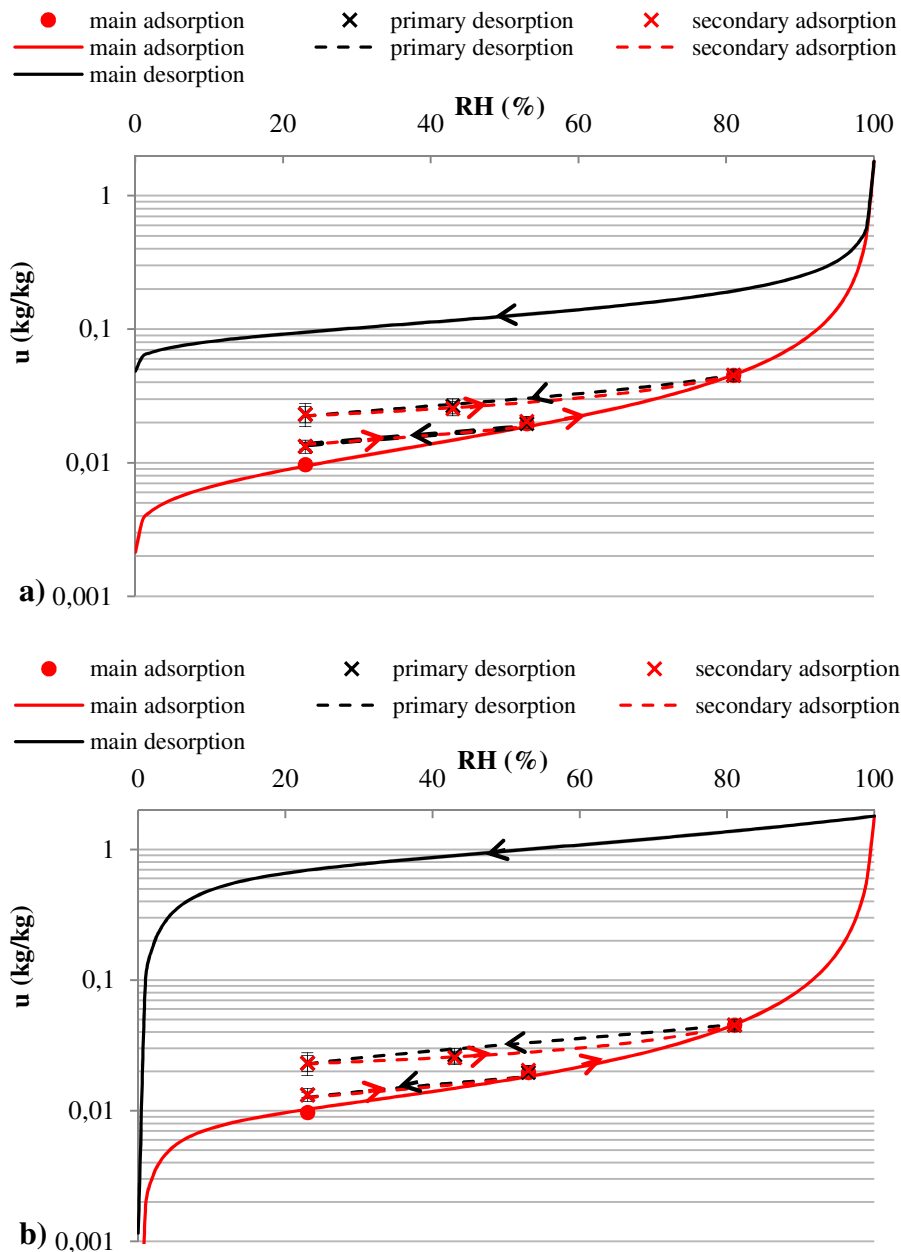

Fig. 3 Experimental (bullets) and numerical results (lines) at the reference temperature of 23°C with VG equation a) and GAB equation b)

Associated with VG equation or with GAB equation, the HH model is in very good agreement with experimental data. It shows its relevance to predict scanning curves in hemp concrete at the reference temperature of 23°C. It gives also hygric capacities (slopes of the curve) close to the experimental ones. The main desorption curve obtained from the GAB equation reaches higher moisture contents than from the VG equation on a large range of relative humidity. Differences are about one order of magnitude.

Associated with the HH model, VG and GAB equations are suitable to predict any scanning curve for the studied relative humidity range.

4.3. Influence of temperature on sorption isotherms

4.3.1. Sorption isotherm at 10°C

Fig. 4 Experimental primary desorption and secondary adsorption measurements (dashed lines and crosses) and experimental main adsorption measurements (solid lines and filled circles)

The experimental results at 10°C and at 23°C are compared in Fig.4. As expected, moisture content decreases when the temperature increases over the studied relative humidity range.

The deviation between moisture content at 10°C and 23°C is slight at high relative humidity.

Whatever the temperature, the hygric capacities for the intermediate scanning curves are lower than the hygric capacities for the main adsorption isotherms. The reduction of hygric capacities is significant at low temperature: the average hygric capacity of the primary desorption curve (calculated over the range [23%RH - 81%RH]) is reduced by 38% at 23°C

instead of 58% at 10°C (over the range [23%RH - 85%RH]). These experimental results highlight the temperature influence on the hysteretic sorption process in hemp concrete.

4.3.2. Isotheric heat of sorption

Mass isotheric heat of sorption q_{st} is plotted on a dual scale u and ratio u/u_m in Fig. 5.

Unlike previous studies [21, 23, 37], no maximal value is highlighted at low moisture contents because the studied range of relative humidities does not cover the range [0%-23%].

For the studied hemp concrete, isotheric heat decreases and tends to the latent heat of condensation l_v (2.45 MJ.kg⁻¹) at a moisture content about 5%, approximately (note that due to experimental uncertainty q_{st} at $u = 4.88$ % is slightly below the value of l_v). This value of 5% is similar to those found in literature for cementitious materials or concrete [21, 23, 37], for example Poyet found $q_{st} \rightarrow l_v$ for $u \approx 4.5$ % [37].

This can be explained by similar specific surface areas for these materials: 59 m².g⁻¹ at 23°C for the studied hemp concrete and 41 m².g⁻¹ at 30°C for the concrete studied by Poyet (in accordance with the values found in literature for cementitious materials between 20 and 200 m².g⁻¹ [47-48]).

The main difference between cementitious materials or concretes and hemp concrete comes from the degree of saturation ($=u/u_{sat}$) for which q_{st} tends to the latent heat of condensation. Whereas Poyet found a degree of saturation about 1 when q_{st} tends to l_v , this value for hemp concrete is about 0.027. This difference is due to the open porosity, very different for both concrete: 72% for the studied hemp concrete and 10-15% for Poyet's concrete.

The three parameters of the PB equation (6) are derived to fit the experimental data: $a = 0.697$ J.kg⁻¹, $b = 0.0886$ kg/kg and $c = 6.443$. For the ThD model, the fitting parameters of the VG equation and the GAB equation are provided in table 4.

Fig. 5 provides the evolution of the isotheric heat for the three numerical approaches: the PB equation, the ThD model associated with the VG equation and the ThD model associated with

the GAB equation. Over the studied range, numerical results performed with the PB equation and the ThD model associated with the VG equation are very close. The ThD model with the GAB equation predicts values of q_{st} slightly higher than the previous models. Over the range [0%RH-23%RH], the deviations are noticeable, especially for ThD model associated with the GAB equation. Numerical results present a maximum value. In accordance with Drouet's assumption for cement-based pastes, the VG equation is unable to represent the maximal isosteric heat [23].

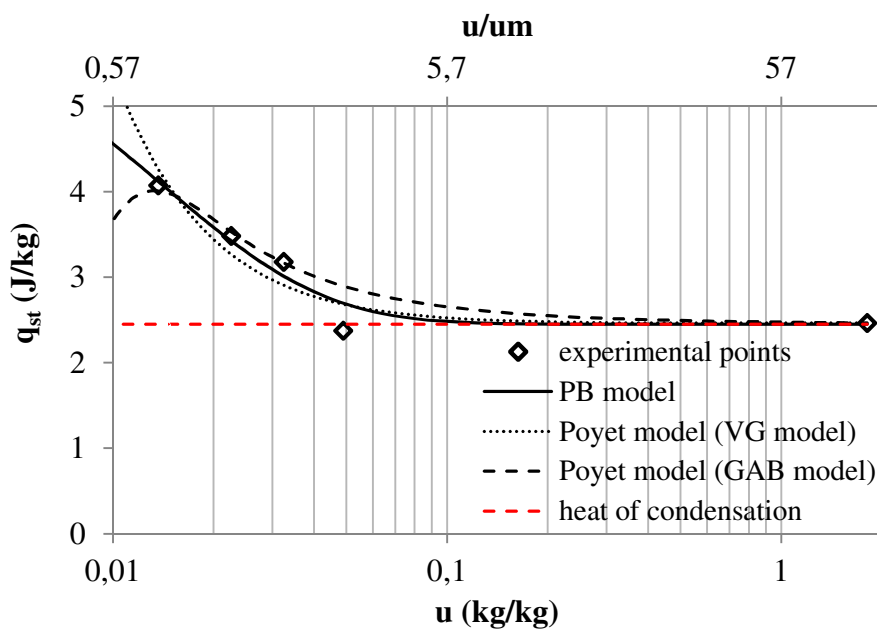

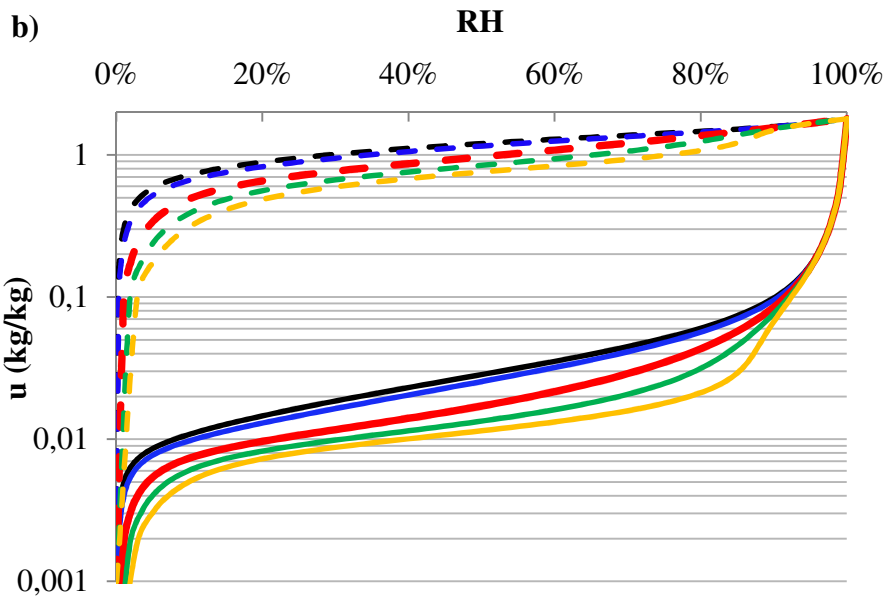

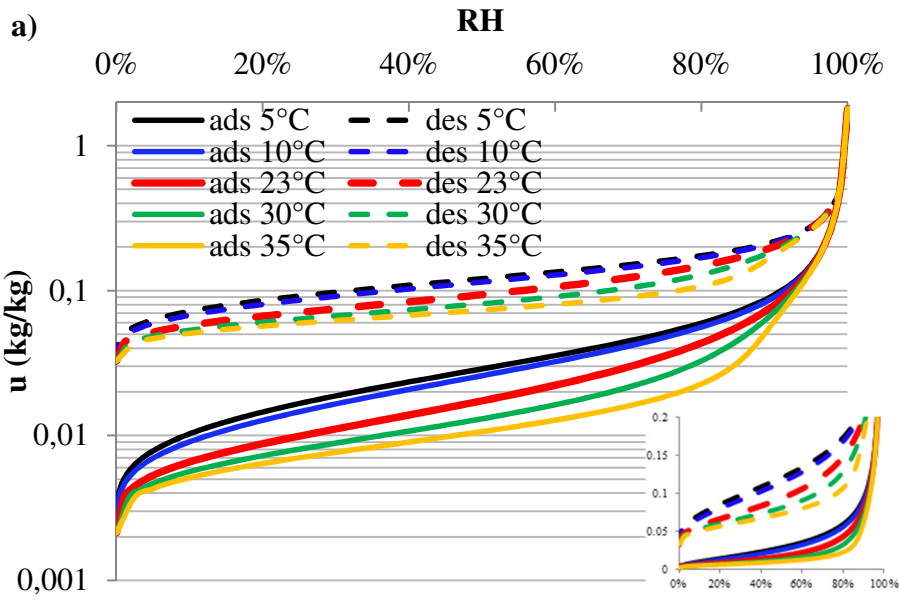

Fig. 5 *Isosteric heat of sorption: experimental and numerical results*

4.3.3. Prediction of sorption isotherms

By using equation (7) and $T_{ref} = 23^{\circ}\text{C}$, the main adsorption and desorption isotherms are derived for temperatures from 5°C to 35°C and are presented in Fig. 6 a) to d). This range of temperatures is representative of the ambient temperature variations in France. In these figures, both PB equation and ThD model are compared using respectively VG and GAB equations.

Figure 6 Main adsorption and desorption isotherms at different temperatures: a) PB equation associated with VG equation, b) PB equation associated with GAB equation, c) ThD model associated with VG equation and d) ThD model associated with GAB equation

For all the numerical simulations, it has to be noted that the hysteresis loop is reduced when temperature increases. As the logarithmic scale used for the moisture content does not highlight this effect of temperature, a no-logarithmic scale in the lower-right corner in Figs. 7

a) and d) is provided. This is in accordance with the hypothesis of Ishida [39] on cementitious materials: the increase of temperature reduces the hysteresis loop.

In Fig. 6 a) and b), the PB equation for both VG and GAB equations causes a significant convergence of the different sorption isotherms at very high relative humidities. This can be explained by the shape of the isosteric heat which tends quickly towards the heat of condensation at high moisture contents. Fig. 6 c) shows the limits of the VG equation. For high temperatures (yellow curve), the VG equation associated with the ThD model is unable to predict moisture content at low relative humidities. Over this range of relative humidities, the isosteric heat obtained reaches very high values (see Fig. 5) which explains the irrelevance of the results. On the contrary, as the GAB equation associated with the ThD model gives an isosteric heat of sorption which presents a maximum value at low moisture content, relevant sorption isotherms are derived whatever the temperature.

4.3.4. Hysteresis and temperature

In this paragraph, the ability of the Huang hysteresis (HH) model associated with the VG and GAB equations to predict the hemp concrete hysteretic behaviour is discussed. At 10°C, the main adsorption curve was experimentally characterised and numerically modelled. The previous section 4.3.3. based on the work of Poyet made possible the determination of the main desorption curve at 10°C. From the main adsorption and a primary desorption curves, the HH model is able to predict any intermediate scanning curve. In Fig. 7, experimental and numerical main adsorption curves and primary desorption curves 85-57-23%RH at 10°C are compared. Associated with the HH model, the VG equation gives a primary desorption curve closer to the experimental one in comparison with the GAB equation. The discrepancies between numerical predictions and experimental results for the GAB equation can be explained by an inaccurate fitting of the main adsorption curves at 85%RH.

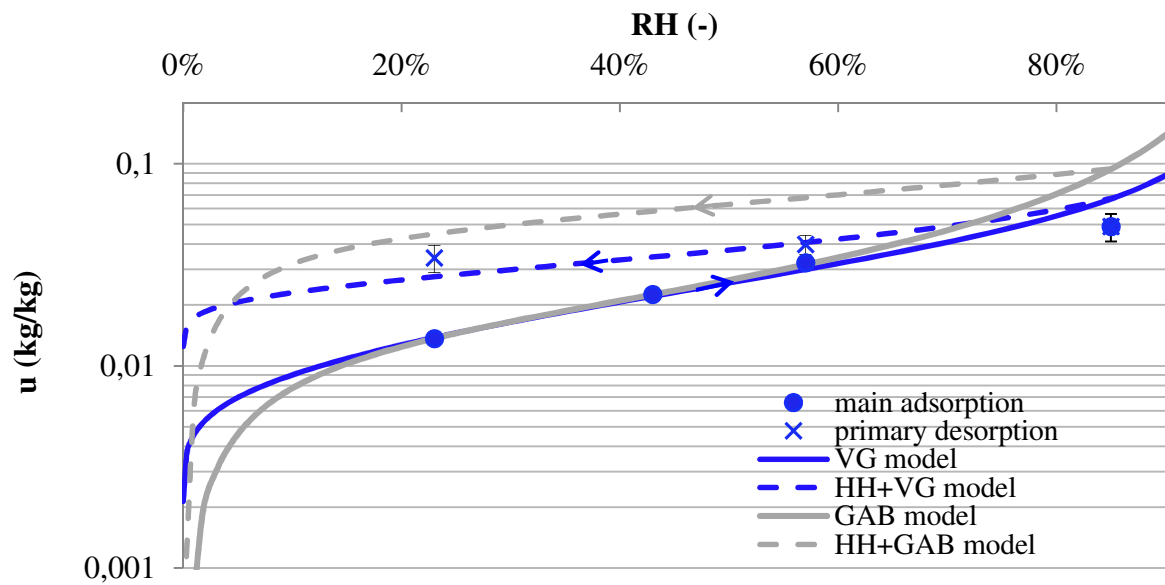

Figure 7 Experimental (bullets) and numerical main adsorption curves (solid lines) and primary desorption curves (dotted lines) at the temperature of 10°C

A comparison between the average experimental and numerical hygric capacities is reported in table 5. It shows that some discrepancies remain but also that the results are relevant. As at 23°C, hysteresis at 10°C decreases the hygric capacity. Both VG and GAB equations associated with the HH model are able to take into account this reduction of hygric capacity. The hygric capacities obtained with the VG equation are closer to the experimental ones than the hygric capacities obtained with the GAB equation. Nevertheless, the reduction of the hygric capacity between the main adsorption and the primary desorption is higher with the GAB equation (39%) than with the VG equation (25%).

	Experimental points		VG equation		GAB equation	
	Main adsorption	Primary desorption	Main adsorption	Primary desorption	Main adsorption	Primary desorption
Hygric capacity (%)	5.7	2.4	8.8	6.6	13.0	8.0
reduction	58%		25%		39%	

Table 5 *Average experimental and numerical hygric capacities at the temperature of 10°C between 23%RH and 85%RH*

This study shows that both VG and GAB equations, associated with the HH model, are able to give relevant results.

5. Conclusion

This paper provides some information concerning both the effects of temperature and hysteresis on sorption processes. These effects were assessed separately then jointly. As expected, experimental moisture content measured at 10°C and 23°C showed that a decrease of temperature results in an increase of moisture content at equilibrium. As at 10°C as at 23°C, experimental scanning curves achieved on hemp concrete show that the hygric capacity is significantly reduced along a scanning curve and point out that hysteresis has a significant influence on the storage or release of moisture in hemp concrete.

The preliminary step to understand the influence of both temperature and hysteresis is to identify an accurate sorption isotherm model. In this paper, GAB and VG equations are investigated. Associated with the HH model, significant differences between VG and GAB equations are observed in the prediction of the main desorption curve but all predicted (desorption as well as adsorption) scanning curves are in good agreement with the experimental data.

The comparison of the numerical results for the prediction of sorption isotherms at different temperatures shows that PB equation can be used as a first approximation in a limited range of temperatures. It has the significant advantage to easily adapt to different sorption models. Nevertheless, it is not physically acceptable since it does not allow representing the physical evolution of the isosteric heat of sorption. On the contrary, the ThD model is able to do so. Associated with the GAB equation, the isosteric heat reaches a maximum value at low moisture content. However the ThD model remains dependent on the chosen sorption model.

The VG equation fails to predict sorption isotherms at high temperatures for low relative humidities. Associated with the ThD model, the GAB equation seems to be the most relevant to predict sorption isotherms.

Finally the use of the HH model associated respectively with VG and GAB equations show some discrepancies between experimental and numerical primary desorption curve 85-23%RH at 10°C. These can be explained by a slight underestimation by the models of the experimental moisture content at 85%RH. However, the results remain relevant and show that the theoretical approach is promising.

The consistency of the calculation depends on the quality and quantity of the experimental results used for the estimation of the isosteric heat. In this way, complementary experimental results at very low and very high relative humidities should improve numerical results.

Acknowledgements

The authors acknowledge financial support of French Research Agency (ANR) and Region Bretagne for the experimental part of this work, within the frame of the projects BETONCHANVRE ANR-06-MAPR-0002 and PRIRECOMATX 2005.

The authors also thank the Easychanvre society for its contribution to the manufacturing of hemp concrete sampling.
