ABSTRACT: Organotin compounds particularly dibutyltin dilaurate, are commonly used as catalysts in coatings or adhesive materials to crosslink silyl modified polymers. However, environmental concerns should lead before 2020 to ban organotin compounds due to their high toxicity. Thus new catalysts must be developed. According to the different types of catalytic systems, i.e. acid, basic or metal containing catalysts, a large variety of candidates should be tested. Thus a high-throughput screening (HTS) method could be an interesting tool for the detection of new efficient catalysts to substitute organotin compounds. We report a global HTS method, compatible with organic amino or acid catalysts libraries, as well as with metal-containing libraries.

KEYWORDS Silyl modified polymers, Cross-linking, High-throughput screening, catalysts.

1. INTRODUCTION

Silyl modified polymers (SMP) are key materials, applied in many applications such as binders for elastic adhesives [1,2], composites [3,4], electrolytes [5] or for coating [6,7] applications. These hybrid polymers are also becoming increasingly common in aeronautical and aerospace applications [8]. They can be used in several other applications due to their adjustable properties [9] such as Young's modulus, tensile strength, thermal, gas barrier and photonic properties. Cross-linking of silyl modified polymers takes place with alkoxy silane groups attached to the ends of polymer chains by hydrolysis and polycondensation with moisture [10,11]. The hydrolysis and condensation reactions occur almost simultaneously and they are in competition with each other. Organotin compounds such as dibutyltin dilaurate (DBTDL) are widely used as catalysts to accelerate the cross-linking of silyl modified polymers with moisture [12]. However, in recent years, the high toxicity of organotin compounds has been proved and the environmental concerns should lead before 2020 to ban organotin catalysts. Thus, several studies were performed in basic or acidic conditions allowing cross-linking of silyl modified polymers without tin catalysts. Indeed, strong acids like $\text{CF}_3\text{SO}_3\text{H}$ [13] or HCl [14] efficiently accelerate the process of hydrolysis. Under basic conditions to deprotonate water, hydroxyl OH^- ions attack the most positively charged atom by nucleophilic reactions [15]. Thus super-bases, like DBU or TBD amines are very efficient to accelerate the reaction and to increase the density of cross-linking. Metal alkoxide catalysts were also reported, in order to generate different cross-linked matrix by comparison with acid or basic organic catalysts.

In all of these studies, the discovery of efficient catalysts has always been obtained by an iterative approach. Each potential catalyst is tested one per one and sometimes at different time scale. This can be time-consuming and does not allow comparison of a large number of catalysts in the same time period, for instance for the same batch of starting material. This classical iterative method has already been described by Bostik [16] for different applications. On the other hand, the high-throughput

experiment is a powerful approach for the fast screening of a large diversity of compounds such as biomaterials [17], inorganic materials [18], polymers [19] or catalysts [20, 21, 22].

Here, we report a semi-quantitative, fast and inexpensive high-throughput screening method based on the visual difference of polymer surfaces when undergoing cross-linking reactions. Indeed, several steps appear during cross-linking reaction (Fig. 1). Prepolymers were used here as starting materials. These stable materials are reactive intermediates which can be cross-linked later. At the beginning of the hydrolysis process, the prepolymer is viscous and when condensation occurs, the viscosity increases. Then, a three dimensional cross-linked structure is obtained. At the end of polycondensation, the surface is solid with a gum texture. According to this point of view, the efficiency of a catalyst could be determined just by touching the surface after a given time t . Indeed, a catalyst will be efficient when the surface is not tacky with a solid gum texture at time t . On the other hand, if the mixture is viscous at time t , the catalyst is inefficient or not sufficiently efficient for the target time t .

Fig. 1: General scheme of hydrolysis and condensation reactions and intermediate states: viscous or solid 3D cross-linked gum.

2. EXPERIMENTAL

2.1. Adhesive materials

Silyl modified polymers are silane based chemicals that contain inorganic and organic moieties which can form polymers exhibiting the beneficial characteristics of both often without many of their disadvantages. Two prepolymers were used for the study: SMP1 and SMP2 which were provided by BOSTIK. They are dimethoxymethylsilane terminated polyethers with a urethane moiety for SMP1 and an alkyl chain for SMP2 (Fig. 2).

SMP1 = dimethoxysilane based polyether with $\text{R} = \text{CH}_2\text{NHCOO}$

SMP2 = trimethoxysilane based polyether with $\text{R} = \text{C}_3\text{H}_6\text{-O}$

Y = CH₃ (SMP1) or OCH₃ (SMP2)

Fig. 2: Scheme of silyl terminated polyethers

2.2. Chemical products

All chemicals were purchased from Sigma Aldrich and were used as received without further purification.

Acid catalysts: Trifluoromethanesulfonic acid (HOTf, >99% wt), Hydrochloric acid (HCl, 37% wt), Methanesulfonic acid (MSA, >99,5% wt), p-Toluenesulfonic acid monohydrate (PTSA, 98% wt), Dodecylbenzenesulfonic acid (DDBSA, 95% wt), Oxalic acid (98% wt), Maleic acid (>99% wt), Malonic acid (99% wt), Chloroacetic acid (99% wt), Glycolic acid (99% wt), Benzoic Acid (>99,5% wt), Acetic acid (>99,7% wt), Propionic acid (>99,5% wt), Lauric acid (>98% wt), Stearic acid (95% wt),

Amine catalysts: 1,8-Diazabicyclo[5.4.0]undec-7-ene (DBU, 98% wt), 1,5-Diazabicyclo[4.3.0]non-5-ene (DBN, 98% wt), 1,5,7-Triazabicyclo[4.4.0]dec-5-ene (TBD, 98% wt), 4-(Dimethylamino)pyridine (DMAP, >99% wt), 1,4-Diazabicyclo[2.2.2]octane (DABCO, >99% wt), Tributylamine (TBA, >98,5% wt), Triethylamine (TEA, ≥99% wt), Pyrazole (98% wt), 1-Methylimidazole (99% wt), Imidazole (>99% wt), Pyridine (>99% wt), 1,2,4-Triazole (98% wt) and Triethanolamine (>99% wt) and

Metal-based catalysts: Dibutyltin dilaurate (DBTDL, 95% wt), Zirconium(IV) propoxide (Zr(IV)ⁿOPr, 70% wt), Zirconium(IV) isopropoxide (Zr(IV)ⁱOPr, 99,9% wt), Zirconium(IV) butoxide (Zr(IV)ⁿOBu, 80% wt), Titanium(IV) propoxide (Ti(IV)ⁿOPr, 98% wt), Titanium(IV) isopropoxide (Ti(IV)ⁱOPr, 97% wt), Titanium(IV) butoxide (Ti(IV)ⁿOBu, 97% wt), Zirconium(IV) acetylacetonate (Zr(IV)acac, 98% wt), Aluminum acetylacetonate (Al(III)acac, 99% wt), Iron(III) acetylacetonate (Fe(III)acac, 97% wt), Copper(II) acetylacetonate (Cu(II)acac, 97% wt), Calcium acetylacetonate (Ca(II)acac, 99,95% wt), Manganese(II) acetylacetonate (Mn(II)acac).

In order to simplify tables and figures, the different catalysts are not reported in full name. When available, only corresponding abbreviations are used.

2.3. Development of high-throughput experiment method with DBU

SMP1 (55g) was introduced into a large plastic vessel (185*95*15mm). As indicated in Fig. 3, a plate containing 96 holes was slowly disposed on the plastic tank to allow the viscous liquid to fill the 96 cavities by capillarity. By this way, 96 identical samples of prepolymer are generated without any transfer by multichannel pipette or individual weighing. Each reactor has an 8mm diameter and 8mm height. Various rates of DBU 0.05% wt (rows G and H), 0.1% wt (rows E and F), 0.3% wt (rows C and D) and 0.5% wt (rows A and B) (0.032mmol to 0.32mmol) were added at the surface of each well with a multichannel pipette. The reaction begins when the mixture is in contact with moisture to allow the development of cross-linking reactions.

2.4. General procedure for parallel screening of catalysts (HTS)

Typically, 1mL tubes (from VWR) are placed in a plate A, containing 96 holes. In a glove box, catalysts (2,25.10⁻⁵mol) and THF (50μL) were added in each tubes. After closing tubes, mixtures were stirred during 1h at room temperature. SMP1 (55g) was introduced in a large plastic vessel (185*95*15mm). Another plate B, containing 96 holes, was slowly disposed on the plastic tank to allow the viscous liquid to fill to 96 cavities by capillarity. By this way, 96 identical samples of prepolymer are generated without any transfer by multichannel pipette or individual weighing. Each reactor has an 8mm diameter and 8mm height. Catalytic systems were then transferred from the plate A into the 96 micro-reactors of plate B with a multichannel pipette to form a film at the surface of

each reactor. The reaction was performed without stirring during 1 hour (or during time t if specified) at room temperature (classical conditions in the laboratory were 55% H_2O and 23°C).

2.5. General procedure for polymerization of SMP1 in bulk

Catalysts ($4,5 \cdot 10^{-4}$ mol) and THF (100 μ L) were added in 1mL tubes (from VWR). Mixtures were stirred during 1h at room temperature. SMP1 (10g) was introduced into a plastic cup (diameter 50mm and height 30mm). Catalytic systems were introduced into the plastic cup and stirred with prepolymer for 1 minute. Surface texture was evaluated by touching the surface every 5 min over a period of one hour, followed by 1 hour for 8hrs and every 24h for 1 week.

2.6. General procedure for polymerization of SMP2 in bulk

Catalysts ($9,5 \cdot 10^{-5}$ mol) and THF (100 μ L) were added in 1mL tubes (from VWR). Mixtures were stirred over a period of 1h at room temperature. SMP2 prepolymer (10g) was introduced into a plastic cup (diameter 50mm and height 30mm). Catalytic systems were introduced into the plastic cup and stirred with prepolymer for 1 minute. Surface texture was evaluated by touching the surface every 5 min over a period of one hour, every 1 hour for 8hs and every 24h for 1 week.

3. RESULTS AND DISCUSSION

3.1. Development and validation of high-throughput screening method

The key point for any HTS approach is to be sure to compare all experiments, accurately performed in the same conditions: a) the amount of material must be identical in each micro-reactor, b) the ratio of catalyst/prepolymer should be the same, c) when different components are mixed together the homogeneity should be guaranteed, d) one should pay attention to avoid cross contamination between micro-reactors. We have developed a new experimental protocol specific for extremely viscous systems. The prepolymer was introduced into a large plastic vessel (185*95*15mm). A plate containing 96 holes was slowly disposed on the plastic tank to allow the viscous liquid to fill the 96 cavities by capillarity. By this way, 96 identical samples of prepolymer are generated without any transfer by multichannel pipette or individual weighing. Catalytic systems were then transferred from a 96 wells plate A to the 96 micro-reactors of plate B with a multichannel pipette. The small size of the individual reactors do not allow an efficient stirring, thus there is a strong risk of having an inhomogeneous reaction mixture. Therefore, we proposed to create a film of catalysts solution at the surface of each well, instead mixing of components. All experiments were able to allow the crosslinking reactions to occur at the surface in contact with moisture under the same conditions for all experiments. Each reactor has an 8mm diameter and 8mm height. Thus, the height prevents any risk of catalyst migration from the surface to the bottom of each well. The screening was performed by touching the surface of each well with a multichannel tip system to visualize the physical state (viscous or gum solid state) every 5 minutes during 1 hour at room temperature. For a given time and only if the catalyst is active, the effective curing of polymers will affect both the surface and the top part of the micro-reactor as the cure depth is related to the square root of time. Thus when the surface is viscous, this means that the catalyst is inefficient. But when a gum aspect occurs (indicating surface and deep curing), this means that the catalyst is efficient. We have validated this high-throughput screening by the classification of catalysts in 3 categories (i.e.; fast, medium and slow activity). Three different rates of a well-known catalyst DBU were applied to simulate three different activity levels of catalysts (Fig. 3).

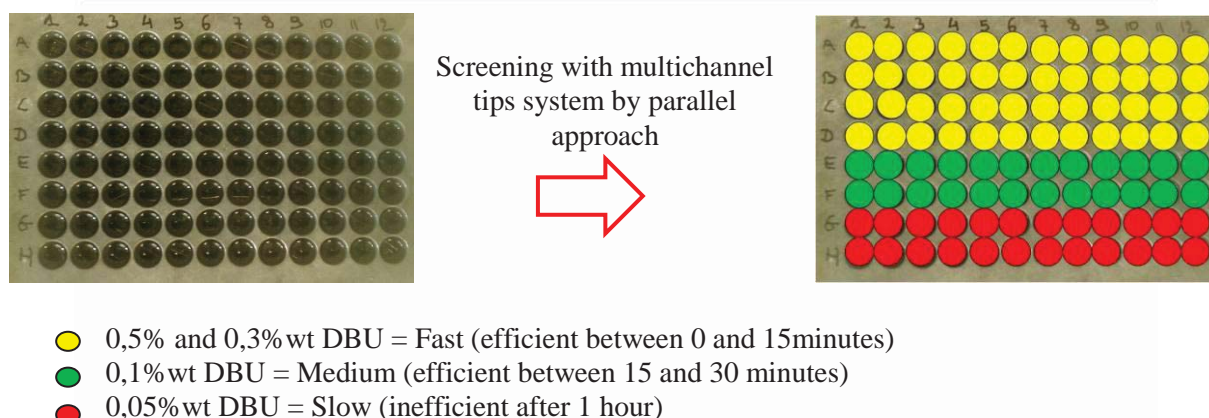

Fig. 3: Scheme of the results obtained during the development of high-throughput screening method

This method allows the fast detection of catalytic systems with different activities. Indeed, we can see the difference with different rates of DBU, 0.5% wt DBU is faster than 0.05% wt DBU which is slower. Moreover, the good reproducibility of the HTS method was validated because for each DBU rate, similar results were obtained. After this validation step, the HTS method was applied on several libraries to compare and to detect efficient catalysts on silyl modified polymers.

3.2. Screening of amines library

Amines and especially tertiary amines are well-known to catalyze polyurethane synthesis, such as DBU and TBD. These catalysts and other amines are also described by Wakabayashi *et al.* in their patent on alkoxy silane terminated polymers [23]. The activation mechanism is similar in these two cases. In the first case, Schwetlick *et al.* [24] showed that tertiary amine allows the activation of alcohol through a base catalysis mechanism to facilitate the addition of this alcohol onto an isocyanate. In the second case, Riegel *et al.* [25] suggested that an amine catalyst increases the dissociation of water to produce nucleophilic hydroxylanions which can attack alkoxy silane groups on a 3-glycidoxylpropyl-trimethoxysilane (GPTS) molecule to accelerate hydrolysis. We can expect that the hydrolysis and condensation mechanisms to crosslink alkoxy silane terminated polymers are the same as base catalysis. To our knowledge, a comparison of the different catalytic systems under the same conditions has not been reported on alkoxy silane terminated polyethers. That is why the efficiency of several amine catalysts was determined by HTS method under the same conditions (temperature and humidity). DBTDL catalyst was used as a reference to compare its activity with amine catalysts (Fig.4).

Fig. 4: a) pKa values of amine compounds and b) their efficiency on SMP1 obtained by HTS method at room temperature

The HTS method allows a fast comparison of different amines under the same conditions. Lower activities, by comparison with the reference tin catalyst DBTDL, were observed for amines with low basicity (pKa 2 to 9 in water) but also for stronger bases such as NEt_3 or NBU_3 (pKa around 10-11 in water). These pKa values in H_2O have been presented by Perrin [26]. In fact only super bases such as DBU, DBN and TBD were really active. The very high basicity of DBN, DBU (pKa at 12) [27] and TBD (pKa at 13.7) [28], induced by the amidinium (DBU, DBN) and guanidinium (TBD) stabilization, seems to be a key point for high catalytic activity. The same differentiation, when considering pKa in acetonitrile, is observed with low activity for bases with pKa lower than 19 (TEA : 18.5 ; DABCO : 18.3) [29] and high activity for bases with pKa higher than 23 (DBU : 23.9 ; DBN : 23.4 ; TBD : 26) [30]. Cramail *et al.* [31] proposed a mechanism which is based on hydrogen bonding between a guanidine like TBD and an alcohol to provide nucleophilic activation. Similarly, in addition to the basicity, the potential participation of the amidinium and guanidinium moiety in the catalytic activation of the alkoxysilane hydrolysis and condensation could be proposed (Fig. 5).

a) General catalytic cycle for the hydrolysis (a) and condensation (b) step of SMP general catalysis of condensation

A guanidine or amidine system such as TBD, DBU or DBN can activate a water molecule (1). The nucleophilic character of hydroxyl was enriched to favor the nucleophilic substitution with an alkoxy-silane group to provide a hydroxyl alkoxy-silane group (2) and the regeneration of catalyst (3). Then, the catalyst system can also increase the reactivity of the hydroxyl alkoxy-silane by hydrogen bonding (4). The condensation between this system and another hydroxy or alkoxy-silane (5) leads to the formation of polymer or a 3D network structure (6).

3.3. Screening of acids library

Acids are also able to catalyze the hydrolysis and condensation of terminal alkoxy-silyl groups. Brinker *et al.* [32] showed that in acid catalysis (HCl) on tetraethylorthosilicate (TEOS), the hydrolysis is favored compared to condensation by H^+ electrophilic attack on alkoxy oxygen. In this case, the silicate gel is not highly crosslinked as compared to base catalysis. Pope *et al.* [33] reported the effect of several inorganic acids such as HF, HCl, HNO_3 , H_2SO_4 on TEOS gel time, considering both hydrolysis and condensation steps. Organic acids catalysts are also very interesting with the opportunity to modulate the Bronsted or Lewis acid properties by playing with the acid functional part (carboxylic, sulfonic groups, ...) or with the other part of the molecule (aliphatic or aromatic acids, electroattractive or electrodonating substituents, ...). For instance, Ni *et al.* [34] showed that *p*-toluene sulfonic acid (PTSA) can be used to catalyze the moisture curing of an organic/inorganic mixture composed of an alkoxy-silane terminated isocyanurate, 1,6-hexamethylene diisocyanate (HDI) and TEOS. Thus, an HTS method could be certainly useful to investigate a large variety of organic acid catalysts and to compare them with DBTDL as reference (Fig. 6).

Fig. 6: a) pKa values of acid compounds and b) their efficiency on SMP1 obtained by HTS method at room temperature

A variety of organic acids were tested, including strong and weak acids, monocarboxylic acids with short and long aliphatic chains or aromatic groups, di-carboxylic acids with different methylene units as well as acids with hydroxyl or chlorine substituents. The different weak acids with relative pKa higher than 1, were medium or not efficient for the cross-linking of SMP1 by comparison with the tin reference catalyst tested under the same conditions. At room temperature and after 1 hour of reaction, all the systems involving weak acids stayed more or less viscous but did not generate the same solid gum aspect like the reference DBDTL. As expected, strong acids with low pKa [35] value such as HOTf (-12), HCl (-7), MSA (-2.6) and PTSA (-1.34) are very efficient crosslinking silyl modified polymers in less than 15 min. These results are coherent with the fact that generally speaking and according to our HTS results, acids with a pKa value equal or less than -1 are efficient systems.

Interestingly, the HTS method led us to detect catalysts with intermediate activity able to generate the solid gum aspect but only after 15 to 30 min. For instance, the HTS method showed that a substitution of the methyl group of PTSA (pKa -1.34) [36] by a longer dodecyl group for the DDBSA (pKa -1) [37] has a great impact on the activity. This effect could be tentatively attributed to higher hydrophobicity induced by the longer dodecyl group by comparison with a methyl group. However, the HTS method also gave an unexpected result as benzoic acid was also detected as a catalyst with medium activity like DDBSA. Only the acidic property seems not enough to explain this result because benzoic acid has a high pKa value (4.2). In comparison with other carboxylic acids like oxalic or maleic acids, it seems that the electronic delocalization through the aromatic ring for the benzoate anionic is a key factor for the catalyst efficiency. Based on the generally accepted hypothesis, indicating that the cross-linking of alkoxy-siloxane is favored when using acids with low pKa value, the benzoic acid would not be evaluated. This result indicated that the HTS approach could be really interesting to detect new acidic catalyst-families.

3.4. Screening of M-(OR) and M(acac) libraries

In some cases, organic catalysts could present some side effects due to the residual catalyst, such as odor diffusion from the material, color modification versus time as well as migration of the catalyst from the 3D cross-linked polymer to another matrix in contact with the polymer. In addition, the organic catalysts could also affect the structure and the morphology of the final reticulated material. For instance, acid catalysts accelerate the hydrolysis step and generate more linear units than base

catalysts. Basic catalysts generate more dense structures and sometimes colloidal containing structures. Thus, the use of metal-containing catalysts, more particularly metal alkoxides, is also of great interest to generate polymers. Blank *et al.* [38] reported several organometallic compounds such as Zr(IV)acac, Zr(IV)OⁿBu and Ti(IV)OⁿBu for the reaction between an isocyanate and a hydroxyl group. Wen *et al.* [39] showed that metallic alkoxides were used as precursors to form an organic/inorganic hybrid network material. In fact, the use of metal alkoxide compounds as efficient catalysts for silyl modified polymers has already been described [40]. Acetylacetonate has often been used as a chelating ligand to decrease hydrolysis and condensation reactions. Several catalysts, such as Al(III)acac, have also been reported to increase the hydrolysis on methyltrimethoxysilane and tetramethoxysilane [41], as well as Fe(III)acac on silyl terminated polymers [42]. However, these reports do not provide a clear comparison between each catalyst for the same substrate, thus it is practically impossible to extract relative reactivity data. In order to compare the efficiency of several metal-containing catalysts we have applied the HTS method and compared to DBTDL as reference under the same conditions (Fig. 7).

Fig. 7 Efficiency of metallic compounds on SMP1 obtained by HTS method at room temperature
 *= heterogeneous mixture

All metallic alkoxides tested here are very efficient on silyl terminated polyethers except for Zr(IV)OⁱPr which is inefficient. It seems that the Zr(IV)OⁱPr is so reactive with moisture that it is too quickly deactivated and has no time to react with Si-OMe bonds inducing an heterogeneous system. In the literature, Pandey *et al.* [43] used a combination of Zr(IV)OiPr and dichloroacetic acid to decrease the reaction of zirconium tetraisopropoxide with moisture. Ti(IV)OⁱPr is effective as a catalyst but this result could be explained by the lower reactivity of Ti(IV)OR than Zr(IV)OR reported by Wen *et al.* [44]. As expected, the results show that acetylacetonate systems with Zr, Ti, Al and Fe are very efficient. Copper and Calcium acetylacetonate systems are inefficient after 1 hour. Interestingly, a manganese system has medium efficiency. This result was very difficult to predict, thus showing the potential benefits of a fast parallel comparison method.

In conclusion, the development of a semi-quantitative high-throughput screening method allows the classification of different catalytic systems according to their efficiency. All catalysts were compared under rigorous identical conditions: geometry and size of micro-reactors, moisture exposure and time for parallel testing. Thus, only differences in catalytic properties will affect the surface or depth curing [45] of polymer. This method is applicable to different types of catalysts like organic bases or acids as

well as for metal-containing catalysts. This can be applied to detect new catalysts by testing 96 catalysts under the same conditions. It is also to spend time on more focused studies, but only on the best candidates for target applications.

3.5. Skinning time of some efficient catalysts in bulk

The HTS method allowed the ranking of different catalytic systems into 3 categories (fast, medium and slow catalysts) according to their relative activity versus the reference catalyst DBDTL. The second step is to measure their 3D solid cross-linking time values compared to DBDTL (**Table 1**) in order to conclude if DBDTL can be substituted.

Table 1. 3D crosslinked gum solid state time of efficient catalysts in bulk by classical method at room temperature on SMP1 prepolymer

Catalysts	Gum solid state time (min)
DBDTL	150
HOTf	instantaneous
HCl	instantaneous
MSA	instantaneous
PTSA	instantaneous
DDBSA	instantaneous
Benzoic acid	4320
DBU	10
TBD	instantaneous
Zr(IV) ⁿ OPr	30
Ti(IV) ⁿ OPr	30
Zr(IV)acac	120
Ti(IV)acac	60
Al(III)acac	105
Fe(III)acac	75
Mn(II)acac	390

Using the same conditions, temperature, humidity and rate of catalytic system, the reactions were performed in bulk condition for 10 g of prepolymer SMP1 and a fast mixing of the mixture. Concerning the acids catalysts HOTf, HCl, MSA, PTSA and DDBSA are much more active than DBDTL as they induced an instantaneous 3D cross-linking. However, these systems are not very useful in bulk conditions or for adhesive applications as a setting time is necessary to generate a homogeneous mixture for bulk reactions and/or to apply the adhesive materials onto a surface. If the final application does not need a very short setting time, the benzoic acid could be applied according to a lower toxicity than the tin catalyst DBDTL. In our application, a setting time of few minutes is necessary to apply adhesive materials on a surface. Benzoic acid could be interesting due to the high toxicity of DBDTL. For bases systems, if TBD generated an instantaneous cross-linking very difficult to control, the DBU catalyst presented very interesting properties with a shorter time for reticulation than DBDTL and a lower toxicity. Metal alkoxides also present high potential as they are faster than the tin catalysts with a lower toxicity. For longer setting time it could also be interesting to use the less reactive metal acac complexes as they are less moisture sensitive than metal alkoxides.

DBTDL	48
HOTf	instantaneous
HCl	0.1
MSA	0,15
PTSA	instantaneous
DDBSA	instantaneous
Benzoic acid	no
DBU	no
TBD	3
Zr(IV) ⁿ OPr	8 < t < 24*
Ti(IV) ⁿ OPr	8 < t < 24*
Zr(IV)acac	72
Ti(IV)acac	8 < t < 24*
Al(III)acac	8 < t < 24*
Fe(III)acac	8 < t < 24*
Mn(II)acac	no

*: Solid gum state reaching time was evaluated at room temperature every 5 min during one hour and every 1 hour until 8h. Days after and early morning, skinning time was evaluated every 24h until 1 week.

Table 2. Skinning time of efficient catalysts in bulk by classical method at room temperature on SMP2

The hits detected by the HTS approach were also tested for another prepolymer SMP2 (**Fig. 2**). In fact, the SMP2 and SMP1 are methoxysilane terminated polymers. In the case of urethane-dimethoxysilane (SMP1), the electron donor (nitrogen atom with free electron pair) is attached to a silicon atom via only one methylene group as spacer. In addition, the methyl group attached to the silicon atom can play an important role by inductive effect. Indeed, the electron density is shifted to the silicon atom and the Si-O(CH₃) bond is weakened. Thus for SMP1, the time of cross-linking reaction decreases due to the activation of alkoxide group. That is why the alkoxide groups split off more easily and hydrolysis is accelerated for SMP1. We envisioned that if the SMP2 is less reactive than SMP1, it is not necessary to screen all of the catalysts again for the SMP2, because an inefficient catalyst on SMP1 will be inefficient too on SMP2. Times to reach the gum aspect of different hits catalysts were determined on SMP2 (**Table 2**). HOTf, PTSA and DDBSA were no longer usable as they induced out of control reticulation. However, HCl and MSA are approximately 200 to 300 times more efficient than DBTDL for the cross-linking of SMP2 and benzoic acid which is slow on SMP1 is inefficient on SMP2. Benzoic acid and DBU did not allow the cross-linking, these results are not surprising as these two catalysts presented a medium activity for the SMP1. In the same way, the TBD, much active for SMP1 is under control for the SMP2 and is 16 times more efficient than DBTDL. Metallic alkoxides and metal acetylacetonate are also more efficient than the tin catalyst, excepted for Zr(IV) acac and Mn(II)acac which are inactive.

CONCLUSIONS

A new HTS method has been developed to allow fast comparison of catalysts for very viscous prepolymers where it has been applied to the study of silyloxane prepolymer cross-linking. The method is compatible with different catalyst families, including inorganic and organic bases, acids and also for metal containing complexes. The method allows to compare and to extract different hits which were analysed in a second step to extract their relative solid state reaching time. DBU, metallic alkoxides and metal acetylacetonate systems could be used to substitute organotin catalysts on silylated activated prepolymers. For inactivated ones, only TBD, HCl, MSA, metal alkoxides and

several metal acetylacetonate systems have shown catalytic activity. This HTS method will be used to detect new catalysts to substitute organotin catalysts to generate ecofriendly adhesive materials.
