HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L'archive ouverte pluridisciplinaire **HAL**, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d'enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.

Cyclodextrin-Sandwiched Hexaphyrin Hybrids. Side-to-Side Cavity Coupling Switched by a Temperature and Redox Responsive Central Device

Mickaël Ménand,^[a] Matthieu Sollogoub,^[a] Bernard Boitrel,^[b] and Stéphane Le Gac^{*[b]}

Abstract: Access to allosteric enzyme mimics that ideally associate communicating compartments for catalysis and regulation is still challenging. Whereas a sandwich "cavity-catalyst-cavity" approach, developed mainly with cyclodextrins and porphyrins, appears promising, its counterpart with hexaphyrins featuring rich conformation, aromaticity and coordination behavior has not been prospected at all. We thus developed sandwich hybrids made of two cyclodextrins triply-linked on each side of a hexaphyrin. The latter displays switchable oxidation states with interconvertible conformations (28 π antiaromatic and 26 π aromatic each adopting rectangular and dumbbell forms). These four states are connected by two orthogonal switches under redox [aromaticity] and thermal [shape] control. It leads to twin compartmentalized confined spaces either locked or unlocked depending on the hexaphyrin conformation, the reversibility of the lock $\leftrightarrow$ unlock transition relying on the hexaphyrin aromaticity. The sandwiched heteroannulene thus behaves as an unprecedented dual-responsive double-latches device. Such hybrid systems open interesting perspectives in allosteric regulation of receptors, catalysts and machineries.

Introduction

The design of allosteric receptors and catalysts able to compete with the efficiency of allosteric enzymes remains a major challenge in supramolecular catalysis.^[1] An ultimate design for a synthetic allosteric catalyst would combine distinct recognition sites displaying asymmetrical confined environments conformationally connected. Each cavity would ensure substrates and effectors selection towards distinct catalytic and regulation functions. In this respect, macromolecular edifices integrating a catalytic center surrounded by two hosting sub-units in a sandwiched manner offer several inherent advantages (Figure 1a, right): (i) they enable compartmentalization of catalytic and regulation functions, (ii) afford a protection of a catalytic metal

center against irreversible deactivation (e.g., formation of μ -oxo complexes), and (iii) strengthen a side-to-side allosteric communication between the sandwiching cavities. Recently, these kinds of architectures featuring "compartmentalized-and-coupled" catalytic and regulation functions have been proposed as blueprint for molecular Turing machines, capable of processing information on a threaded polymer chain.^[2]

cavity” associations (Figure 1a, left) involve singly linked cavities serving as anchoring points for a substrate presenting a specific domain to the catalytic site. As a result, these cavities rather operate a passive conformational restriction deprived of active allosteric regulation.^[3] Still, an effective sandwich approach involving cavities with distinct roles remains to be explored.

Cyclodextrins are well known to meet the enzyme pockets requirements in hybrid architectures.^[4] Their cyclic oligo-saccharide skeleton provides naturally occurring chiral and water soluble structure with a confined hydrophobic environment.^[5] Besides, porphyrins are key catalysts extensively developed and used to support enzyme modelling studies.^[6] However, only a small number of sandwiched receptors/catalysts integrating either cyclodextrins and/or a central porphyrin have been reported and generally with modest yields.^[7-12] Furthermore, only a couple of examples from Naruta and Nolte groups showed allosteric communication between the porphyrin-separated cavities, owing to induced-fit guest inclusion processes.^[11,12] Although the porphyrin macrocycle displays some flexibility, we reasoned that such a sandwich design would be more modular with other porphyrinoids able to adopt major conformational changes,^[13] thus allowing more effective coupling of the cavities. Hexaphyrins are good candidates since they can adopt different conformations (rectangular [R], dumbbell [D], triangular [T], Möbius [M], figure-eight [8], Figure 1d),^[13d,f] with a possible control over their interconversion by external stimuli: (de)protonation,^[14] solvent polarity,^[15] temperature,^{[15c],[16]} metal coordination,^[17] and more importantly, redox control of their π -conjugated circuits (i.e. 26π vs. 28π electrons: $R[26]H/M[28]H$ Figure 1b, left).^[15b] As such, hexaphyrins have a great, yet unexplored potential as switchable components in the design of molecular machineries.^{[18],[19]}

In this context, we recently prepared a new type of hybrid edifices made of a hexaphyrin unit triply-linked on one side by a cyclodextrin (HCD, Figure 1b, right).^[20] This unique association generates a confined dissymmetrical environment between the rectangular hexaphyrin and the primary rim of the cyclodextrin. Interestingly, a rectangular-to-triangular shape shifting process was observed with protonated forms, allowing to tune the size and shape of the confined space and thus the molecular recognition properties of HCD (Figure 1c).^[21] In another recent example, a hexaphyrin triply-linked to a tris(2-aminoethyl)amine (tren) unit showed rectangular-to-Möbius conformational changes triggered by a cooperative two-guest binding process to a buried zinc metal ion.^[22] In spite of their triple linkage, the dynamic behavior of these two capped hexaphyrins stresses the high propensity of this heteroannulene to undergo profound and rapid conformational changes affording new types of adaptative molecular receptors. We thus envisioned that hexaphyrins doubly-capped by cyclodextrin units in a sandwich manner (CDHCD, Figure 1d) may undergo similar conformational reorganization allowing to change the shape of the sandwiched edifice, and thus the coupling of the cavities.

We therefore describe herein the first synthesis of doubly-capped hexaphyrins, affording compartmentalized-yet-coupled confined spaces matching a unique orthogonal control of the central hexaphyrin conformation and aromaticity.

Results and Discussion

1. Synthesis

The targeted cyclodextrin-sandwiched hexaphyrins (CDHCDs) possess an $(AB)_3$ -type *meso*-substitution pattern. In the case of “unconstrained” hexaphyrins, this pattern is achieved by reacting an equimolar mixture of an aldehyde A and a dipyrromethane B.^[23] The hexaphyrin frame is the major one among porphyrin and higher homologues, without scrambling (Scheme 1a, [3+3] macrocyclization). In the case of HCD hybrids, a related strategy consisting in the condensation of a cyclodextrin-tris-aldehyde platform (ACE pattern) with three equivalents of dipyrromethane (Scheme 1b top, [1+3] macrocyclization), afforded a hexaphyrin capped on one side by a cyclodextrin unit.^[20] This reaction was also attempted the other way, i.e. by reacting a cyclodextrin-tris-dipyrromethane platform with three equivalents of aldehyde (Scheme 1b, bottom), leading to the same HCD hybrids.^[24] The present study investigates the ensuing strategy consisting in a

Scheme 1. Macrocyclization strategies for $(AB)_3$ -type *meso*-substituted hexaphyrins, (a) without tripodal unit, (b) with a single tripodal cavity on one face, (c) with tripodal cavities on both faces. The notation $[x+y]$ refers to the number of subunits A and B involved in the macrocyclization step.

Scheme 2. Synthesis of $\text{CD}[26]\text{HCD}$ and $\text{CD}[28]\text{HCD}$ through a [1+1] condensation of **1** and **2**. Representations of the equilibrated rectangular and dumbbell conformations are depicted in detailed and simplified views (perspective and top views in grey insets; C_2 symmetrically related parts colored in red and blue). Labelling of the two conformers is differing according to the location of the C_2 symmetry axis (see labels on the right).

[1+1] macrocyclization between two complementary cyclodextrin platforms (Scheme 1c). The corresponding doubly-capped hexaphyrins are thus obtained through the condensation of the cyclodextrin-tris-aldehyde **1** and its related cyclodextrin-tris-dipyrromethane adduct **2** (Scheme 2).^[25]

The cyclodextrin-tris-aldehyde **1** was synthesized from the native α -cyclodextrin following a five steps procedure as previously described.^[20] Condensation of **1** with a large excess of pyrrole, catalyzed by trifluoroacetic acid (TFA), afforded the cyclodextrin-tris-dipyrromethane adduct **2** in 66% yield. The [1+1] macrocyclization between **1** and **2** was achieved in dichloromethane at 0.01 M concentration using a catalytic amount of methanesulfonic acid ($[\text{MSA}] = 0.002 \text{ M}$). The monitoring of the

reaction by mass spectrometry indicated rapid completion (ca. 1h). Subsequent oxidation of the cyclodextrin-sandwiched hexaphyrinogens with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) followed by chromatography purification afforded the $\text{CD}^{\text{R}}[28]\text{HCD}$ hybrid (Scheme 2) which was however difficult to separate from oligomeric side products. To facilitate its purification, this 28π form was further oxidized in its 26π one by a second treatment with DDQ. Surprisingly, two fractions of different polarity were isolated by chromatography (0.7% and 2.7% overall yield). HRMS (ESI-TOF) of both fractions afforded the same mass ($[M+2\text{H}]^{2+}$: m/z 2910.2570) corresponding to $\text{CD}[26]\text{HCD}$ hybrids. As described below, their ^1H NMR spectra display different signatures corresponding to the rectangular

(major) and the dumbbell (minor) conformers (**CD^R[26]HCD** and **CD^D[26]HCD** respectively, Scheme 2). Subsequent reduction of these fractions with NaBH(OAc)₃ afforded their corresponding 28 π reduced forms with analytical purity (81% yield for **CD^R[28]HCD**, and 40% yield for **CD^D[28]HCD** following a specific pathway – *vide infra*). It is worth to note that conformational transitions occur between the rectangular and dumbbell CDHCDs for both oxidation states (Section 3), lengthening the purification steps. Although CDHCDs are obtained with modest yields, access to sandwiched expanded porphyrins is unprecedented and competes with strategies used for doubly-capped porphyrin edifices.^{[8d],[9],[10]}

2. Characterization

The UV-vis-NIR absorption spectra of these CDHCDs show strong similarities with those of the closely related HCDs (Figure 2b,d). Indeed, the rectangular form of both families in their (28)26 π states exhibit characteristic Hückel (anti)aromaticity. **CD^R[26]HCD** shows a strong Soret-like band ($\lambda_{\text{max}} = 568$ nm) with four Q-like bands reaching the NIR region ($\lambda_{\text{max}} = 723, 784, 919$ and 1050 nm). This characteristic pattern denoting an aromatic character is almost superimposable to those of **R[26]HCD**, **R[26]H** and the Möbius aromatic **M[28]H** (Figure 2b,d). Conversely, **CD^R[28]HCD** displays a UV-vis spectrum typical of antiaromatic hexaphyrins in line with its related **R[28]HCD** (*i.e.* broad and smeared absorption bands at $\lambda_{\text{max}} = 488$ and 583 nm, deprived of Q-like bands; Figure 2d).^[26] Compared to their rectangular isomers, the 26 π and 28 π dumbbell conformations exhibit broader UV-vis spectra of similar signatures. **CD^D[26]HCD** displays a less intense Soret-like band at 580 nm and broad Q-like bands between 700 and 1000 nm, while **CD^D[28]HCD** displays large and smeared absorption bands at $\lambda_{\text{max}} = 500$ and 568 nm. The erosion of intensity and broadening of the Q-like bands might arise from a distortion of the π -conjugation pathway of the hexaphyrin core (see below).^[27] Hence, **CD^D[26]HCD** and **CD^D[28]HCD** also exhibit aromatic and antiaromatic character, respectively, but of weaker intensity compared to their rectangular forms.

The circular dichroism spectra of all CDHCD hybrids show Cotton effects involving the hexaphyrin Soret-like bands, indicating a clear chirality transfer from the surrounding cyclodextrins (Figure 2a,c). In the case of the rectangular conformations of singly- and doubly-capped hybrids, similar patterns are observed with bisignate signal splitting of the Soret-like bands broader for 28 π antiaromatic vs 26 π aromatic compounds.^[28] Besides, doubly-capped rectangular hexaphyrin chromophores experience an enhanced chiral environment compared to their singly-capped ones (for **R[26]HCD** vs. **CD^R[26]HCD**: $\Delta\epsilon_{585} \approx 40$ vs. 100 M⁻¹.cm⁻¹, Figure 2a; and for **R[28]HCD** vs. **CD^R[28]HCD**: $\Delta\epsilon_{573} \approx 30$ vs. 40 M⁻¹.cm⁻¹, Figure 2c). In stark contrast, the dumbbell conformation of CDHCD hybrids display less intense Cotton effects that are in line with the weaker absorption intensity and/or a less efficient chirality transfer.

Analysis of the ¹H NMR spectra (CDCl₃) of the four isolated CDHCDs allowed unambiguous structural and aromaticity characterization (Figure 3). The four CDHCDs display C₂

Figure 2. (a) Circular dichroism and (b) UV-vis-NIR spectra of **R[26]H**, **R[26]HCD**, **CD^R[26]HCD** and **CD^D[26]HCD** in CH₂Cl₂. (*) Contamination with traces of **CD^R[26]HCD**. (c) Circular dichroism and (d) UV-vis-NIR spectra of **M[28]H**, **R[28]HCD**, **CD^R[28]HCD** and **CD^D[28]HCD** in CH₂Cl₂. Blue spectra denote aromatic character and red spectra denote antiaromatic character.

symmetrical ¹H NMR spectra, the C₂ axes being located within the average plane of the hexaphyrins with different orientation according to the conformation. Whereas the rectangular species exhibit a transversal C₂ axis across the two proximal inverted pyrroles ($\pi 2/\pi 5$ *inward*), the dumbbell ones exhibit a longitudinal C₂ axis across the two distal pyrroles located on the short sides ($\pi 2/\pi 5$ *outward*, Scheme 2, simplified views in inset). The NMR spectra display two characteristic sets of signals, a first one accounting for the two C₂-symmetrically related cyclodextrins (2 × 6 different glucose units [A to F], 2-6 ppm crowded region) and a second one spanning over ~25 ppm corresponding to half of the hexaphyrin (2 × 6 β -pyrrolic protons and 2 × 1 or 2 NH protons). For the sake of conciseness, NMR description focuses on characteristic groups of protons discussed hereafter.

(i) rectangular species

The hexaphyrin protons of the doubly-capped hybrids experience the same field effects as their singly-capped homologues (Figure 3, b vs. a and e vs. f, red and blue boxes). The ¹H NMR spectrum of **CD^R[26]HCD** (Figure 3b) displays two upfield shifted singlets (π -in: -3.35 and -3.21 ppm) and four downfield doublets (π -out: 8.42 to 9.34 ppm) corresponding to the four *inward* β -pyrrolic protons ($\pi 2$ and $\pi 5$) and the eight *outward* β -pyrrolic ones ($\pi 1$, $\pi 3$, $\pi 4$, and $\pi 6$) respectively. The reverse distribution is observed for **CD^R[28]HCD** (Figure 3e), with the two singlets shifted at 20.43 and 20.01 ppm (π -in) and the four doublets ranging from 2.49 to 3.12 ppm (π -out). These chemical shifts witness pronounced diatropic and paratropic ring current for respectively the 26 π and 28 π conjugated states, shielding/deshielding the inside and

Figure 3. ^1H NMR spectra (600MHz, CDCl_3 , 300K) of (b) $\text{CD}^{\text{R}}[26]\text{HCD}$, (c) $\text{CD}^{\text{D}}[26]\text{HCD}$, (d) $\text{CD}^{\text{D}}[28]\text{HCD}$ and (e) $\text{CD}^{\text{R}}[28]\text{HCD}$. For the sake of comparison, selected signals of the four CDHCD species and their HCD analogues (a and f) are depicted as ticks in coloured boxes.

deshielding(/shielding) the outside of the hexaphyrin frame. In conjunction with UV-vis absorption spectra, these NMR observations confirm the respective aromatic and antiaromatic characters of $\text{CD}^{\text{R}}[26]\text{HCD}$ and $\text{CD}^{\text{R}}[28]\text{HCD}$ hybrids. In addition, the chemical shifts of the sandwiching cyclodextrins follow the same trend as those of HCDs.^[20] Notably, the marked characteristic shifting of the protons belonging to the O-6 benzyl group of unit A (" $\text{CH}_2\text{OBn-A}$ ", Figure 3, b vs. a and e vs. f, green boxes) indicates an offset of the cavities from the center of the hexaphyrin, the latter protruding over the two C_2 -symmetrically related A glucose units (Scheme 2, cartoon in inset).^[20] This particular topology inherently associates an NNCC coordination box to a specific cavity. Indeed, the two faces of a given NNCC coordination box experience different environments: one axial coordination is hindered to some extent by the cyclodextrin's wall whereas the opposite axial coordination is surrounded by a confined space (see below). As a consequence of the C_2 -symmetry of CDHCDs, the "left" and "right" NNCC coordination sites are thus coupled to divergent cavities ("bottom" and "top"), offering a unique opportunity to study potential side-to-side communication across the hexaphyrin through allosteric events.

(ii) dumbbell species

In the case of the dumbbell CDHCDs (Figure 3c,d), the twelve β -pyrrolic protons (two singlets and four doublets) are located at the periphery of the hexaphyrin and experience deshielding(/shielding) due to diatropic(/paratropic) ring currents (π -out: 7.36 to 8.57 ppm for $\text{CD}^{\text{D}}[26]\text{HCD}$ and 4.70 to 5.71 ppm for $\text{CD}^{\text{D}}[28]\text{HCD}$). The dumbbell conformation is also supported by the characteristic shifts of the two introverted *meso*-aromatic substituents located in the pinched region of the macrocycle (Figure 3c,d, brown boxes). These aromatic protons are unevenly shielded(/deshielded) with a strong effect towards the protons in *ortho* position to the hexaphyrin link [$\delta(\text{H}_o^{\text{H}}) = 1.71$ ppm for $\text{CD}^{\text{D}}[26]\text{HCD}$ and 13.42 ppm for $\text{CD}^{\text{D}}[28]\text{HCD}$]. This indicates that the introverted *meso*-aromatic groups stand almost orthogonally to the hexaphyrin mean plane. The *inner* orientation is expected to generate important steric hindrance, likely compensated by a distortion of the hexaphyrin, and this may explain the weaker diatropic and paratropic ring currents of the dumbbell species.^[29] Thus, in accordance with the UV-vis spectra, a marked deviation from planarity likely reduces effective π -

Figure 4. Side view and apical view from the cyclodextrin secondary rim of the optimized geometry of (a) $\text{CD}^{\text{R}}[26]\text{HCD}$ and (b) $\text{CD}^{\text{D}}[26]\text{HCD}$ (Avogadro software, UFF parameters; benzyl groups were omitted for the modeling). The calculated Connolly solvent-accessible surface areas are depicted in green and red. The latches cartoons at the center illustrate the locking/unlocking principle.

conjugation leading to a “weakening” of both aromaticity ($\text{CD}^{\text{D}}[26]\text{HCD}$) and antiaromaticity ($\text{CD}^{\text{D}}[28]\text{HCD}$). In contrast to the rectangular CDHCDs, no evidence was observed for an offset of the sandwiching cyclodextrins vs the dumbbell [26/28] hexaphyrins.

The molecular modelling of the rectangular and dumbbell conformers (26 π oxidation state) showed no significant variation with the geometric features deduced from UV-vis and NMR analysis (Figure 4). Connolly solvent-accessible surfaces were calculated, evidencing a major difference in hosting potential. For $\text{CD}^{\text{R}}[26]\text{HCD}$, the hexaphyrin is sandwiched by two identical and dissymmetrical confined spaces, each delineated by the hexaphyrin plane, the three linkers, and the cyclodextrin primary rim (green color, Figure 4a). These confined spaces are roughly similar to that of $\text{R}[26]\text{HCD}$, large enough to include two molecules of MSA^- .^{[20],[21]} In contrast, the self-inclusion of two *meso*-aryl groups in the dumbbell conformation severely restricts this solvent-accessible volume (red color, Figure 4b). Although the cyclodextrin cavities are preserved, their “direct” interaction with the hexaphyrin is no longer possible. Thus, the *meso*-aryl groups act as latches locking or unlocking (dumbbell or rectangular conformation respectively) the access to both the hexaphyrin core and the associated confined spaces. Were transitions between these conformations to be controlled, the central hexaphyrin would become a switchable device for tuning the CDHCD host-guest properties in a coupled manner.

3. Conformational switching

As stated in Section 1, the separation of the rectangular and dumbbell conformations of CDHCDs was made difficult because of conformational transition between the two forms. We thus investigated the dynamic behavior of these conformations through ^1H NMR spectroscopy in CDCl_3 . VT-NMR of $\text{CD}^{\text{R}}[26]\text{HCD}$ and $\text{CD}^{\text{D}}[26]\text{HCD}$ (230 to 330 K) showed little changes of their chemical shifts indicating minor deviation from the rectangular and dumbbell conformations over the explored range of temperature (SI). However, for each conformer, traces of the other one were produced at high temperature (330 K) during the analysis. Evolution of these separated samples ($\text{CD}^{\text{R}}[26]\text{HCD}$ or $\text{CD}^{\text{D}}[26]\text{HCD}$) for a prolonged period of time at 330 K allowed to reach the same ratio of the two conformers, evidencing thermodynamic equilibrium ($R/D = 70:30$, Figure 5b and SI). In contrast, heating a pure sample of $\text{CD}^{\text{R}}[28]\text{HCD}$ at 330 K in CDCl_3 for 15 hours did not produce any trace of $\text{CD}^{\text{D}}[28]\text{HCD}$ conformer, whereas heating $\text{CD}^{\text{D}}[28]\text{HCD}$ in the same conditions led progressively to a full conversion of the dumbbell form into the rectangular one (Figure 5a and SI). Accordingly, the two conformers are not in equilibrium but rather correspond to kinetic (dumbbell) and thermodynamic (rectangular) products.

The kinetic profile of the latter transformation was then examined monitoring the time dependent conversion of $\text{CD}^{\text{D}}[28]\text{HCD}$ into $\text{CD}^{\text{R}}[28]\text{HCD}$. Surprisingly, the transformation did not follow a first order rate law, the kinetic profile being “too linear” (Figure 5c and SI). Instead, the data better fitted with a putative model involving a catalytic step with a catalyst loading estimated at 0.5 mol% (SI). Further experiments should be performed to identify the nature of the expected catalyst and its mode of action.^[30]

Table 1. Kinetic constants (k / h^{-1}) and activation free energies ($\Delta G^\ddagger / \text{kcal.mol}^{-1}$) for $\text{CD}^{\text{D}}[26]\text{HCD} \rightleftharpoons \text{CD}^{\text{R}}[26]\text{HCD}$ equilibrium.

Figure 5. Simplified illustrations of (a) the D→R conversion of **CD[28]HCD** and (b) the D⇌R equilibrium of **CD[26]HCD**. Rotation of the pyrroles for both transformations are depicted in the insets. Kinetic plots following the time dependant concentration variations of D (●) and R (▼) forms in CDCl_3 at 330 K for (c) **CD[28]HCD** and (d) **CD[26]HCD** (fitting curve in red). (e) VT- ^1H NMR stacks (600 MHz, sealed tube) of R and D equilibrated mixture of **CD[26]HCD** from 330 to 360 K in CDCl_3 (red box) and THF-d_8 (blue box). The regions selected show π -1/3 $^{\text{Ar-in}}$ (D: ●) and π -4/6 $^{\text{S}}$ (R: ▼) evolution (labelling in Scheme 2).

Conversely, the kinetic profiles of the equilibration pathways concerning **CD^D[26]HCD** and **CD^R[26]HCD** (D⇌R starting from D or R) fitted well by a first-order rate law (Figure 5d and SI). The corresponding kinetic constants (k_1 and k_{-1} respectively) measured in both CDCl_3 and THF-d_8 allowed to calculate the free energies of activation (Table 1, $\Delta G^\ddagger$, SI). Indeed, the isomerization pathway between the rectangular and dumbbell forms involves a formal *in/out* inversion of two opposite pyrroles (red pyrroles in Figure 5b) assisted by NH hydrogen bonding. Concomitantly, their neighboring *meso*-aromatic groups facing each other undergo a reverse *out/in* inversion. The energy barriers of these transformations (Table 1, $\Delta G^\ddagger_{330} = 23.8$ to 25.6 kcal.mol $^{-1}$) are of the same amplitude as the one previously determined for the related singly-capped **R[26]HCD** ($\Delta G^\ddagger_{360} = 23.3$ kcal.mol $^{-1}$). This latter undergoes a so-called isomorphic fluxionality converting the rectangular conformation into another degenerate rectangular one through the formal rotation of four pyrroles.^[20] The energy barriers of the D⇌R equilibrium are sufficiently high to allow the isolation of each conformer at room temperature and keep them kinetically stable at low temperature (4°C).

We then examined the equilibrated proportion of the two conformers between 330 and 360 K in CDCl_3 and THF-d_8 (Figure 5e).^[31] Interestingly, in both solvents, the D⇌R equilibrium is pushed towards the dumbbell conformer with increasing

Figure 6. Global network showing the pathways between the four states of CDHCD and the triggering action. Individual circular dichroism signatures are depicted in the middle in association with the locking and aromatic states.

temperature. The effect is more pronounced in THF-d_8 with R/D ratios at 360 K up to 30:70 vs 50:50 in CDCl_3 . The equilibrium constants ($K = [\text{R}]/[\text{D}]$) derived from the measured ratios allowed to draw the van't Hoff plot (SI) and determine the energy parameters engaged in the rearrangement (Table 2). The corresponding enthalpic gain is probably arising from a more efficient double hydrogen bonding network (hexaphyrin N-core) in the less distorted rectangular conformation, while the entropic cost might be ascribed to the higher capability of the rectangular conformer to encapsulate solvent molecules (locked vs. unlocked cavities, Figure 4). Remarkably, this thermal tuning of the hexaphyrin conformation transforms CDHCD architecture into the first device in which the dynamical control of the open and closed states is performed by an expanded porphyrin.

Once these dynamic processes analyzed, we devised a strategy to access the **CD^D[28]HCD** isomer (kinetic product) otherwise difficult to obtain through direct synthesis. The strategy involves an equilibration of the 26 π isomers at high temperature followed by a rapid quenching and a reduction of the dumbbell-enriched mixture (SI). Hence, **CD^R[26]HCD** was heated at 90°C for 15 min in THF pushing the ratio towards the dumbbell conformer. A subsequent rapid cooling from 90°C to –78°C allowed to freeze the equilibrium and kinetically trap the dumbbell-enriched mixture (R/D $\approx$ 30:70 [NMR ratio, SI]). The latter was further reduced at 0°C with tetra-*n*-butylammonium borohydride (TBABH $_4$) affording the corresponding mixture of 28 π conformers with a *ca.* 1:1 dumbbell/rectangular ratio. Upon separation, **CD^D[28]HCD** was isolated in 40% yield (analytical sample). The

combination of the temperature-controlled equilibrium of 26π conformers with their 28π redox conversions not only gives an access in reasonable yield to kinetic species ($\text{CD}^{\text{D}}[\text{28}]\text{HCD}$) but also delineate a global reaction network connecting all CDHCDs as shown below.

4. Global reaction network and one-way cycling

Figure 6 summarizes the aromaticity and conformational changes connecting the four CDHCDs. On the one hand, the 28π and 26π states are redox interconvertible regardless of their conformation. This allows independent antiaromatic-aromatic transitions (left/right). On the other hand, transitions between the locked and unlocked states (D/R conformations) depend on the aromaticity of the hexaphyrin (top/bottom). Both states of the 26π aromatic hybrids are in equilibrium and temperature controlled, whereas those of the 28π antiaromatic hybrids are irreversibly connected (kinetic locked state and thermodynamic unlocked state).

Thus, aromaticity and conformational transitions can be orthogonally addressed (redox vs. temperature control) offering an interesting combination for the development of multi-addressable allosteric receptors. Obviously, a mutual influence of such a reaction network with hosting and coordination properties of the CDHCD hybrids is expected. In addition, these four hybrids exhibit markedly different chiroptical signatures in circular dichroism (Figure 6), offering an additional opportunity for orthogonal chiroptical switches.^[18b]

To exemplify these orthogonal transitions, we attempted to realize a one-way cycle over the global reaction network (Figure 7 and SI). The following experiment was monitored by ^1H NMR spectroscopy in a sealed tube: first, $\text{CD}^{\text{R}}[\text{28}]\text{HCD}$ was fully converted to $\text{CD}^{\text{R}}[\text{26}]\text{HCD}$ by treatment with DDQ (Figure 7a,b); then, equilibration following the heating/freezing procedure described above, afforded $\text{CD}^{\text{R}}[\text{26}]\text{HCD}$ as the major species (R/D = 40:60, Figure 7c); subsequent reduction with TBABH_4 gave $\text{CD}^{\text{D}}[\text{28}]\text{HCD}$ without modification of the ratio (R/D = 40:60, Figure 7d); finally, heating the sample converted the last mixture into the initial $\text{CD}^{\text{R}}[\text{28}]\text{HCD}$ as a single product (Figure 7e). This process corresponds to the following sequential transitions: antiaromatic/unlocked $\rightarrow$ aromatic/unlocked $\rightarrow$ aromatic/locked $\rightarrow$ antiaromatic/locked $\rightarrow$ antiaromatic/unlocked.

Conclusions

In conclusion, the grafting of a cyclodextrin unit on each side of a hexaphyrin, leading to 2:1 sandwich edifices, has been successfully realized. Such doubly-capped hybrid structures are unprecedented with expanded porphyrins.

On the one hand, the CDHCDs share similar properties with their parent 1:1 HCD hybrids: (i) the hexaphyrin preferably adopts a rectangular shape for both the $26/28\pi$ -conjugated states. Thus, aromatic and antiaromatic compounds, featuring markedly different chiroptical properties, are accessible and interconvertible; (ii) the cyclodextrin units are offset from the hexaphyrin center, in opposite directions, and thus specifically coupled to adjacent NNCC coordination sites. This particular

Figure 7. One screw cycle over the four CDHCDs (bottom), monitored by ^1H NMR spectroscopy (top; $\text{THF}-d_6$, 276 K). Conditions: see the SI. (*) residual solvents and impurities.

arrangement affords two apical confined spaces, both compartmentalized and connected by the central hexaphyrin unit. On the other hand, CDHCDs exhibit unique conformational features characterized by the dumbbell conformation observed for both $26/28\pi$ -conjugated states. A second set of aromatic and antiaromatic compounds is thus accessible with, again, different chiroptical properties. In addition, the dumbbell conformations severely restrict the confined spaces due to the introversion of two *meso*-aromatic groups.

Four different CDHCDs are accessible and connected through a reaction network orthogonally addressed by temperature changes (dumbbell-to-rectangular transitions triggering locked-unlocked states) and/or redox reactions (26π -to- 28π -conjugated transitions controlling aromaticity-antiaromaticity and thus the reversibility of the above conformational transitions). Remarkably, a one-way cycle through the reactions network allowed the sequential transition over the four CDHCDs. These architectures are thus switchable devices controlled by a thermal and redox responsive central hexaphyrin unit. The associated conformational reconfigurations of the whole structure connect the cavities in different manners. Hosting and coordination properties of these various hybrids are currently under investigation with a particular interest towards their mutual influence to target multi-addressable allosteric receptors and catalysts.

Experimental Section

FULL PAPER

Royale with cheese. New sandwich compounds made of a hexaphyrin doubly-capped by cyclodextrins have been developed. The central hexaphyrin behaves as a dual-responsive device, coupling the cavities with different operating modes in switchable manners, depending on both its (anti)aromaticity and conformation. The accessibility of two compartmentalized-and-coupled confined spaces is locked/unlocked in a reversible way or not, opening interesting perspectives in allosteric regulation.
