ABBREVIATIONS

AD: Atopic dermatitis

MTX: Methotrexate

CYC: Cyclosporine

ABSTRACT

Introduction: Cyclosporine and methotrexate are the two preferred first-line immunosuppressive treatments in atopic dermatitis. The aim of this study was to compare the treatment profiles of methotrexate and cyclosporine in daily practice as the first-line immunosuppressive treatment in atopic dermatitis, using two survival analyses, “drug survival” (time on the drug) and “post-drug survival” (time between two drugs).

Methods: Retrospective study including patients with moderate-to-severe atopic dermatitis treated with methotrexate or cyclosporine as the first-line immunosuppressive treatment. The reasons for discontinuation of treatment were collected: controlled disease, treatment failure, side event pregnancy and non-compliance. “Drug survival” and “post-drug survival” analyses were performed using the Kaplan Meier method and predictive factors were analyzed using uni- and multivariate Cox regression analyses.

Results: 56 patients, among whom 25 patients treated with cyclosporine and 31 with methotrexate (median age: 34 ± 15 years) were included between 2007 and 2016. Reasons for discontinuation were not significantly different between “controlled disease” and other reasons ($p=0.11$). The median “drug survival” was significantly longer for methotrexate (23 months) than for cyclosporine (8 months) ($p<0.0001$). Six months from baseline, 93% of patients treated with methotrexate were still being treated vs 63% among patients treated with cyclosporine. The median of “post-drug survival” was significantly longer for methotrexate (12 months) than for cyclosporine (2 months). Only treatment with CYC was a predictive factor for decreased “drug survival” and “post-drug survival”.

Conclusion: This is the first direct comparison between methotrexate and cyclosporine as first-line immunosuppressive treatments for moderate to severe atopic dermatitis in daily practice. We evidenced two different treatment profiles: the duration of methotrexate administration is longer than that of cyclosporine. “Post-drug survival” could be a new tool to

assess the maintenance of effect of a drug after withdrawal in atopic dermatitis, and more broadly in chronic skin disease.

INTRODUCTION

Atopic dermatitis (AD) is one of the most common chronic inflammatory skin diseases in both children and adults with a prevalence of 10 to 20%^{1,2}.

In most of cases, AD patients are mainly managed in primary care with the following treatment strategies: daily emollient application, use of anti-inflammatory topical therapy including topical steroids and topical calcineurin inhibitors and avoidance of individual triggering factors for mild AD, and conventional topical anti-inflammatory therapy with a proactive approach and phototherapy for moderate AD. In the more severe AD patients i.e patients with chronic active disease or subintract flares with high impact on quality of life, immunosuppressive treatment is currently used.

The major therapeutic challenges in immunosuppressive treatment for chronic skin diseases are efficacy and safety in the long-term. Furthermore, efficacy should optimally include persistent drug effect after its discontinuation. In a pragmatic approach to managing AD patients with chronic and severe disease, two questions can be raised: “how long can a patient remain on an immunosuppressive treatment in conditions that are both safe and efficient? (i.e. the time on drug)” and “how long can a patient be free of immunosuppressive treatment after its discontinuation? (i.e. the time between two drugs)”. Drug survival analysis has recently been used to explore the first issue but data on the second issue is lacking.

Cyclosporine (CYC) and methotrexate (MTX) are the two preferred first-line immunosuppressive treatments in moderate-to-severe AD in France, probably with different treatment profiles in clinical practice. Only CYC is approved as the first-line immunosuppressive treatment for severe atopic dermatitis in France. But MTX is an off-label immunosuppressive treatment option for patients with severe atopic dermatitis. In clinical practice in France, cyclosporine and methotrexate are both the first-line immunosuppressive treatment of choice currently used for patients with atopic dermatitis requiring a first-line immunosuppressive^{3,4}.

The objective of this work was to compare the treatment profiles of MTX and CYC as first-line immunosuppressive treatment in AD patients, using two survival analyses: “drug survival” and “post-drug survival” analyses.

MATERIALS AND METHODS

Study design and setting

This retrospective longitudinal study was performed among children and adult patients with moderate-to-severe atopic dermatitis treated with at least one immunosuppressive drug, either MTX or CYC, between January 2007 and December 2016, at three French dermatology departments (Rennes University Hospital, Saint-Brieuc Hospital and Le Mans Hospital).

Participants

All patients treated with MTX or CYC as first-line immunosuppressive treatment for AD were included for the survival analysis.

In a first step, electronic data were used to search for patients with moderate-to-severe AD: at Rennes University Hospital, patients were selected from the biomedical database of the hospital (eHOP)⁵ by entering the terms: “atopic dermatitis” or “eczema” or “atopic eczema” and “MTX” or “CYC”; at Saint-Brieuc and Le Mans Hospitals, patients were selected from the French hospital discharge database (PMSI, medicalized information system program), by using the ICD-10 code L20 “atopic dermatitis”. Patients with moderate-to-severe AD are usually hospitalized at least once to introduce the first-line immunosuppressive treatment at Saint-Brieuc and Le Mans Hospitals.

In a second step, a total of 546 medical visit records of selected patients were read to check that MTX or CYC were given for AD at Rennes University Hospital and to select patients with MTX or CYC for AD at Saint-Brieuc and Le Mans hospitals. A total of 490 patients were excluded for the following reasons: CYC or MTX prescribed for other diseases at Rennes University Hospital (n=274); no prescription of CYC or MTX for AD at Saint-Brieuc et Le Mans (n=198); initiation of treatment before 2007 (n=6); first-line systemic treatment of AD not CYC or MTX (n=4); unknown date of initiation of CYC or MTX treatment (n=2); and treatment duration with MTX or CYC under 2 months (n=6).

Variables

A standardized questionnaire was used to collect the following information: gender; age at initiation of first-line of immunosuppressive treatment; weight; personal and familial history of atopy; previous treatments for AD (anti-inflammatory topical treatments, i.e. corticosteroids and calcineurin inhibitors, or phototherapy); age at AD onset; immunosuppressive treatments following first-line immunosuppressive treatment with MTX

or CYC (i.e. mycophenolate mofetil, azathioprine, omalizumab, intravenous immunoglobulins and alitretinoin), starting dose, maximum dose during treatment, date of start and end of each treatment line and reason for discontinuation (controlled AD, primary or secondary failure, pregnancy, non-compliance and side effects). We defined two categories of dosage for each treatment: for MTX: $\leq 15\text{mg}$ weekly and $> 15\text{mg}$ weekly; and for CYC: $\leq 3.5\text{mg/kg/day}$ and $> 3.5\text{mg/kg/day}$. For children under 12 years, a high dose of MTW was defined as $> 0,25\text{ mg/kg}$ weekly. An interruption of treatment longer than three months was considered as a discontinuation of treatment. Adverse events were collected and classified as serious side effects (death, hospitalization, disability, or life-threatening consequences) and other side effects (separated into two categories of outcome: discontinuation of the treatment and continuation of treatment).

Drug survival analysis

Patients treated with MTX and CYC as first-line immunosuppressive treatment for AD were included in the “drug survival” analysis. Survival analysis is a method for analysing data for the occurrence of an event. Drug survival is the time patients remain on MTX or CYC, and the event is the discontinuation of MTX or CYC. The event date considered was the date of discontinuation of treatment whatever the reason. Time data was censored when patients were lost to follow-up or were still being treated at the end of data lock. The probability of continuing the treatment with MTX or CYC was analysed using the Kaplan-Meier method. The following possible determinants of “drug survival” for first-line immunosuppressive treatments were studied: gender, age at the initiation of first-line immunosuppressive treatment, treatment used, maximum dosage of MTX or CYC as defined below.

Post-drug survival analysis

Patients who discontinued MTX or CYC as first-line immunosuppressive treatment for AD were included in the “post-drug survival” analysis. “Post-drug survival” was defined as the time between the end of the first-line immunosuppressive treatment with MTX or CYC and the second-line immunosuppressive treatment (time between two drugs). The event date considered was the date of initiation of the second-line immunosuppressive treatment. Time was censored when patients were lost to follow-up or did not start a second-line immunosuppressive treatment at the end of data lock. The probability of starting second-line immunosuppressive treatment after the discontinuation of first-line immunosuppressive treatment was analysed using the Kaplan-Meier method. The following possible determinants

of “post-drug survival” were studied: age at onset of disease, gender, long duration of first-line treatment, treatment used, high dose of the first-line treatment, and discontinuation of the first-line treatment because the disease was under control. “Drug survival” and “post-drug survival” are presented in Fig. 1.

Statistical analyses

Drug survival was analyzed using the Kaplan-Meier survival curves. Two survival curves were defined and analyzed separately: the date of treatment discontinuation (providing “drug survival”) and the date of initiation of the second-line treatment after discontinuation of MTX or CYC (providing “post-drug survival”). Differences in drug survival between the two groups were analyzed using the log-rank test. A descriptive analysis of qualitative data was performed, calculating numbers and percentages for each category, while quantitative data was described by calculating means, minimum and maximum values. We performed Cox regression analysis to identify predictive determinants for “drug survival” and “post-drug survival”. The variables with a p -value < 0.2 in the univariate analysis were entered into the multivariate model. A p -value under 0.05 was considered significant. Analyses were stratified according to center. The χ^2 test was used to compare the reasons for treatment discontinuation. Statistical analyses were performed with R software version 3.3.0.

The study was approved by Ethics Committee of Rennes University Hospital (n°17.32) and patients gave their signed informed consent for the anonymous use of their medical information in the context of a medical research, in accordance with the principles of the Helsinki Declaration.

RESULTS

Patients and treatment characteristics

In all, 56 patients with moderate-to-severe AD treated with CYC or MTX as first-line immunosuppressive treatment were included between 2007 and 2016. The baseline characteristics of these patients are shown in Table 1. The mean age of patients was 34 ± 15 years and the gender ratio was 1:1. For 89% of patients, the onset of AD occurred during childhood. All patients received topical anti-inflammatory treatments including topical steroids and topical calcineurin inhibitors; 57% of the patients were treated with phototherapy. In addition, 62% of the patients had been hospitalized for AD, including 9 patients for serious skin infections.

Among the 56 patients with moderate-to-severe AD treated with CYC or MTX as first-line immunosuppressive treatment, 25 patients (44.6%) received CYC and 31 patients (55.4%) received MTX. The mean starting dose was 2.2 ± 0.63 mg/kg daily for CYC (n=24) and 11 ± 3.63 mg weekly for MTX (n=30). The mean maximum dose during treatment was 3.6 ± 1.25 mg/kg daily for CYC (n=22) and 16 ± 4.59 mg weekly for MTX (n=28). The details are given in the supplementary data.

The Sankey diagram shows the different sequences of first, second, third and subsequent courses of immunosuppressive treatments for the 56 patients with moderate-to-severe AD treated with CYC or MTX as a first-line immunosuppressive treatment (Fig. 2).

At the end of data collection, 18 patients treated with MTX and 20 patients treated with CYC had discontinued the first-line immunosuppressive treatment. The reasons for discontinuation of the first-line immunosuppressive treatments are presented in Table 2. The causes of discontinuation were obtained for 17 patients receiving MTX and 14 patients receiving CYC. Ten patients (55%) treated with MTX and 3 patients (16%) treated with CYC discontinued the treatment for controlled disease. Four patients (22%) treated with MTX and 6 patients (31%) treated with CYC discontinued the treatment following either primary or secondary failure. Only 3 (16%) patients discontinued CYC because of side effects (not serious) and no patient discontinued MTX because of side effects. There was no difference between cyclosporine and methotrexate for the reasons of treatment discontinuation (“controlled disease” and other reasons) (p -value=0.11).

Drug survival

Comparison of drug survival for MTX and CYC as first-line immunosuppressive treatments.

The comparison of drug survival between MTX and CYC using Kaplan-Meier curves is presented in Fig. 3. The median drug survival for CYC and MTX as first-line treatment was 8 and 23 months respectively (log rank $p < 0.0001$). Six months after initiation of MTX, 93% of patients were still being treated versus 60% of patients on CYC. Twelve months after the initiation of MTX, 71% of patients were still being treated versus 38% of patients on CYC.

Table 3 shows the determinants of drug survival for MTX and CYC as first-line immunosuppressive treatment according to univariate and multivariate Cox regression analyses. There was no association between drug survival for MTX or CYC and age at initiation of treatment, gender and a high doses of MTX or CYC. CYC was the only predictive factor for shorter drug survival in univariate and multivariate models (HR 7.44; 95% CI 1.97–28.13; $p < 0.003$).

Post-drug survival

Comparison of post drug survival for MTX and CYC as first-line immunosuppressive treatments

Thirty-eight patients discontinued the first-line immunosuppressive treatment (n=18 for MTX; n=20 for CYC). The median duration of “post-drug survival” was 12 months for MTX and 2 months for CYC (log rank $p = 0.014$) (Fig. 4). Six months after discontinuation of MTX, 28% of the patients required a second-line treatment, whereas 75% required it after discontinuation of CYC.

Six months after discontinuation because of disease control (n=10 for MTX and n=5 for CYC), no patient required second-line treatment after first-line immunosuppressive treatment with MTX versus 75% of patients after first-line treatment with CYC (log rank $p = 0.5$). Six months after discontinuation for other reasons (n=8 for MTX and n=15 for CYC), 50% of the patients required second-line treatment after first-line immunosuppressive treatment with MTX versus 80% of patients after CYC (log rank $p = 0.13$).

Table 4 shows the determinants of “post-drug survival” in univariate and multivariate Cox regression analyses. A long duration of the first-line treatment (HR=1.13; IC95% (0.46-2.76); $p = 0.79$) and discontinuation of the first-line immunosuppressive treatment following disease control (HR=0.76; IC95% (0.26-2.19); $p = 0.60$) were not associated with a shorter time between two drugs (“post-drug survival”). CYC was the only predictive factor for shorter “post-drug survival” (HR=3.00; IC95% (0.83-10.89); $p = 0.09$).

DISCUSSION

This is the first direct comparison in daily practice between MTX and CYC in moderate-to-severe AD as first-line immunosuppressive treatments. Further to this, we were able to describe two treatment profiles using an approach based on “drug survival” (time on drug) and “post-drug survival” (time between two drugs). “Drug survival” was significantly longer for MTX (median=23 months) than for CYC (median=8 months) and “post-drug survival” was also significantly longer for MTX (median=12 months) than for CYC (median=2 months).

Comparative studies between two common systemic treatments in AD are a major research priority and a concern for clinicians⁶, as highlighted by a recent systematic review⁷. A recently published phase 3 randomized non-inferiority study comparing MTX at 15 mg weekly and CYC at 2.5 mg/kg/d showed a rapid onset of CYC efficacy with a larger proportion of patients achieving SCORAD 50 at 8 weeks (42% vs 8%). Increasing the dose of MTX to 25 mg weekly resulted in a similar clinical improvement to that obtained with high doses of CYC of 5 mg/kg/d at week 20⁸. A pediatric study of forty children suggested similar treatment responses between CYC and MTX⁹. There is at present one multicentric randomized controlled trial in the UK comparing MTX and CYC among children with moderate-to-severe AD¹⁰.

The efficacy and safety results of these clinical trials are difficult to generalize to patients in daily practice settings because of strict inclusion criteria. Clinical studies often include better-fitted and more compliant patients. The severity profile of patients in trials is also different and does not reflect indications for treatment in daily clinical practice. For instance, Goujon *et al.* study included a severe profile of patients (80% of patients with baseline SCORAD index > 40), resulting in early treatment discontinuations. Retrospective studies in real-life settings in AD are complementary to clinical studies, providing additional information such as duration of treatment, the hierarchy of common treatments used in clinical practice and the prevalence of side events in “real world” patients with more comorbidities than in clinical trials. Few studies have been conducted in AD^{11,12}. Knowledge in these fields can be helpful in clinical decision-making in addition to clinical trials. The present study gives objective information about the time on MTX and CYC, which are both immunosuppressive treatments commonly used in daily practice for the treatment of

moderate-to-severe AD. The comparison for “drug survival” and “post-drug survival” evidences significant differences between MTX and CYC in AD, suggesting their different treatment profiles.

Unlike studies on efficacy, disease activity scores are not widely used in daily practice for the assessment of AD disease. Drug survival analysis, which concerns time on treatment, is an objective and informative outcome, especially for retrospective studies. Events that lead to withdrawal of a treatment are also informative, such as effectiveness, failure and side events. Therefore, drug survival analysis is increasingly used to assess long-term and chronic treatments such as biotherapies in rheumatology and dermatology^{13,14}. Long drug survival is assumed to attest of an adequate balance between efficacy and safety for both clinicians and patients. Drug survival analysis is also useful to identify predictive factors for long duration of treatment.

It can also be of interest to analyze the time patients remain without treatment until a subsequent line of immunosuppressive treatment is required in chronic diseases. Indeed, treatment discontinuation often occurs in chronic skin diseases without the need for a switch of treatment, especially in AD. “Post-drug survival” is a new approach that includes both the benefit of the first-line immunosuppressive treatment and the time free from any immunosuppressive treatment, which is a main concern for patients.

Some limitations to this study should be discussed. It is a retrospective study with a small sample size. It is also limited by some missing data concerning the causes of treatment discontinuation. Retrospective screening in medical records implies an information bias, but a uniform and extensive search was performed to minimize it.

The median “drug survival” of 8 months for CYC reported here is consistent with two recent drug survival studies^{15,16}. In contrast, the median “drug survival” for MTX is estimated at 23 months in this study, more than twice a previous result¹⁷. The drug survival for MTX is significantly longer than for CYC. This finding could be explained by a particular immunomodulatory effect of MTX, a use of MTX for less severe AD, or a different safety profile between MTX and CYC. MTX discontinuation because of side events was not reported in this study. The shorter time on the drug for CYC could suggest rapid efficacy on AD. However long-term CYC use is restricted by safety concerns, including potential

nephrotoxicity and risk of skin cancer, with a treatment duration usually between 9 and 12 months^{18,19}. “Drug survival” can be influenced by various factors: the physician’s prescribing behaviors, patient satisfaction, comorbidities, safety profile of the treatment, effectiveness, and availability of alternative treatments¹³.

As regards the causes of MTX and CYC discontinuation, the proportion of discontinuations for “disease under control” among patients treated with CYC is lower in the present study than in others (16% vs 22% and 45%)^{15,16} while the proportion of discontinuations for “disease under control” for patients with MTX is in line with previous findings (55% vs 49%)¹⁷. This could suggest a higher severity profiles among patients treated with CYC in our population. The interpretation of the result is limited by the small number of reasons for discontinuation of the first-line treatment.

“Post-drug survival”, which relates to the probability of starting a second line of treatment after withdrawal of a first treatment, has not been studied in AD, and is a major concern for physicians and patients. The result evidencing a shorter “post-drug survival” for CYC (median= 2 months) than for MTX (median= 12 months) could suggest a suspensive effect of CYC without a maintenance effect in the long-term, a more severe disease profile in patients treated with CYC, or treatment discontinuation because of a serious side effect. “Post-drug survival” can be influenced by a remanence effect of the first-line treatment, by patient or physician decision to start a subsequent treatment, by duration and dosage of the previous treatment or by the availability of efficient alternative treatments. “Post-drug survival” could reflect “time to relapse” which has already been studied in studies on CYC in AD^{20,21}. However, the definition of “relapse” mainly depends on the measurement of disease activity, which is often difficult to obtain in retrospective studies, whereas “post-drug survival” is easily measurable and remains an objective outcome.

The differences in drug survival and post-drug survival between CYC and MTX point to two treatment profiles: on the one hand, the effect of MTX tends to correspond to immunomodulatory treatment, compared to CYC where the effect is more suspensive. Managing severe AD requiring immunosuppressive treatments is difficult. Recent guidelines have proposed a strategy to help the physician’s clinical decision to initiate an immunosuppressive treatment for chronic and refractory AD²². However, no recommendation on the withdrawal of an immunosuppressive treatment in AD is provided. Indeed, the

assessment of this disease is complex: clinical skin scores are used in clinical trials but are too time-consuming for the physicians in clinical practice, and they are static measurements of severity not taking account of the overall course of AD, with flares and sometimes spontaneous remissions. Drug survival studies are expanding in the field of management of chronic disease. We suggest including “post-drug survival” for the purpose of better assessment in the use of immunosuppressive treatments, particularly in chronic skin diseases. Taking account both approaches, “drug survival” and “post-drug survival”, our findings suggest that MTX may present a better treatment profile for the long term control of moderate-to-severe AD, which is a well-identified challenge for clinical research and care²³.

This is the first direct comparison of MTX and CYC in moderate-to-severe AD in daily practice using “drug survival”, and a new concept of “post-drug survival”. Two treatment profiles have been identified: treatment duration of MTX is longer than that of CYC and the time to initiation of a new treatment is also longer after MTX withdrawal. “Post-drug survival” could be a new tool for better assessment of the maintenance effect after immunosuppressive treatment discontinuation in chronic skin disease.

Table 1. Patient characteristics

<i>Patient characteristics at baseline</i>	Overall population (N = 56)	Patients treated with MTX (N = 31)	Patients treated with CYC (N = 25)
<i>Age at initiation of the first-line systemic treatment — year</i>	34 ± 15	35 ± 15	32 ± 16
<i>Male gender — no. (%)</i>	28 (50)	14 (45)	14 (56)
<i>Personal history of atopy — no. (%)</i>			
Asthma (n = 44)	38 (86)	20 (83)	18 (90)
Rhinitis (n = 37)	20 (54)	9 (50)	11 (58)
Food allergy (n = 23)	13 (56)	4 (40)	9 (69)
Conjunctivitis (n = 37)	14 (38)	4 (23)	10 (50)
Keratoconus (n = 1)	1 (100)	0 (0)	1 (100)

<i>Family history of atopy</i> (n = 43) — no. (%)	20 (46)	9 (41)	11 (52)
<i>Age at onset of AD</i> (n = 46) — no. (%)			
0-9 years	41 (89)	21 (84)	20 (95)
10-18 years	2 (4)	1 (4)	1 (5)
19-35 years	2 (4)	2 (8)	0 (0)
> 35 years	1 (2)	1 (4)	0 (0)
<i>Serious infection (defined as requiring hospitalization)</i> (n = 46) — no. (%)	9 (20)	5 (18)	4 (21)
<i>Comorbidities</i> — no. (%)			
Cardiovascular (n = 9)	3 (33)	2 (28)	1 (50)
Obesity (n = 9)	1 (11)	1 (14)	0 (0)
<i>Previous treatments</i> — no. (%)			
Phototherapy (n = 32)			
Total sessions (n = 21)			
< 10	2 (9)	1 (10)	1 (9)
10 à 19	9 (43)	3 (30)	6 (55)
20 à 39	4 (19)	2 (20)	2 (18)
40 à 59	4 (19)	2 (20)	2 (18)
60 à 79	1 (5)	1 (10)	0 (0)
80 à 100	1 (5)	1 (10)	0 (0)
Type of phototherapy (n = 22)			
UVA1	1 (5)	1 (10)	0 (0)
UVBTLO1	15 (68)	5 (50)	10 (83)
PUVA	3 (13)	3 (30)	0 (0)
Other	3 (13)	1 (10)	2 (17)
Hospitalization for AD (n = 32) — no. (%)	20 (62)	7 (54)	13 (68)

All percentages are given for patients with data available

Table 2. Reasons for discontinuation of the first-line immunosuppressive treatment.

<i>Reasons of discontinuation of the first-line immunosuppressive therapy</i>	MTX	CYC	<i>p</i> -value
	N = 18 (%)	N = 20 (%)	0.11
Controlled AD	10 (56)	3 (16)	
Primary failure	2 (11)	4 (21)	
Secondary failure	2 (11)	2 (10)	
Side effects	0 (0)	3 (16)	
Non-compliance	1 (6)	1 (5)	
Pregnancy	2 (11)	1 (5)	
Unknown	1 (6)	6 (30)	

Table 3. Determinants of “drug survival” of first-line immunosuppressive treatment by univariate and multivariate Cox regression analysis.

Variable	Univariate model			Multivariate model		
	HR	95% CI	<i>p</i>	HR	95% CI	<i>p</i>
Age*	0.98	0.96 - 1.00	0.11	0.97	0.94 – 1.00	0.14
Gender†	1.12	0.56 - 2.28	0.74	1.38	0.56 – 3.38	0.48
Drug CYC (ref : MTX)	9.20	3.04 – 27.80	< 0.001	7.44	1.97 – 28.13	0.003
High dose of treatment‡	1.99	0.86 – 4.65	0.11	0.68	0.24 – 1.96	0.48

* At the initiation of the first-line treatment

† Male as reference

‡ Defined as a mean maximum dose of CYC > 3.5 mg/kg daily, MTX > 15 mg weekly and for children under 12 years old, MTX > 0,25mg/kg weekly

Analysis stratified according to center. Data are given as hazard ratios (HR) (95% confidence interval).

Table 4. Determinants of “post-drug survival” for first-line immunosuppressive treatment by univariate and multivariate Cox regression analysis.

Variable	Univariate analysis			Multivariate		
	HR	95%CI	<i>p</i>	HR	95%CI	<i>p</i>
Age*	1.03	0.99 – 1.08	0.12	1.04	0.99 – 1.09	0.06
Gender†	1.94	0.66 – 5.70	0.22	-	-	-
Long duration of first-line treatment‡	1.13	0.46 – 2.76	0.79	-	-	-
Drug CYC (ref : MTX)	2.42	0.69 – 8.50	0.17	3.00	0.83 – 10.89	0.09
High dose of treatment§	1.19	0.37 – 3.82	0.77	-	-	-
Discontinuation of first-line treatment because of controlled disease	0.76	0.26 – 2.19	0.60	-	-	-

*At the initiation of the first-line treatment

†Male as reference

‡Defined as a duration of treatment > 12 months for MTX and > 6 months for CYC

§Defined as a mean maximum dose over treatment with CYC > 3.5 mg/kg daily, MTX > 15 mg weekly and for children under 12 years old, MTX > 0,25mg/kg weekly

Analysis stratified according to center. Data are given as hazard ratios (HR) (95% confidence interval).

Figure 1. Definition of “drug survival” and “post-drug survival”.

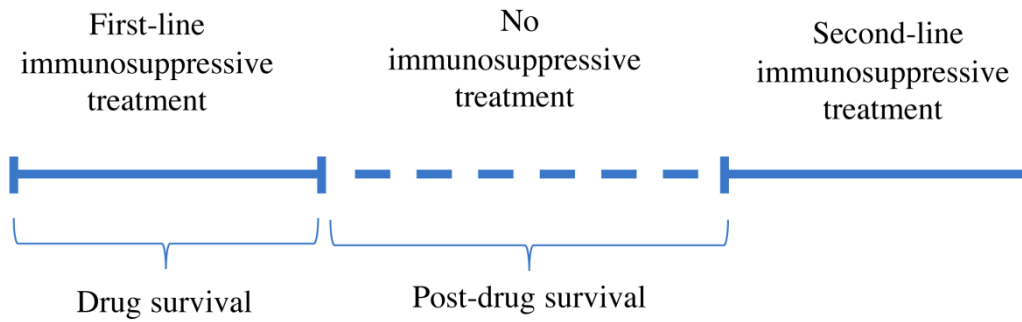

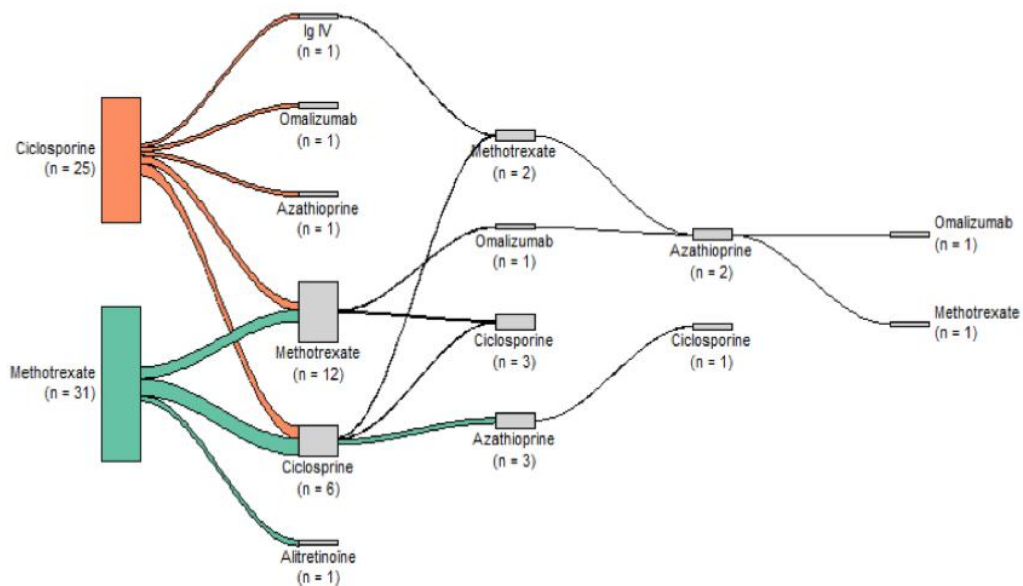

Figure 2. Sequences of treatment lines for immunosuppressive treatments: Sankey diagram

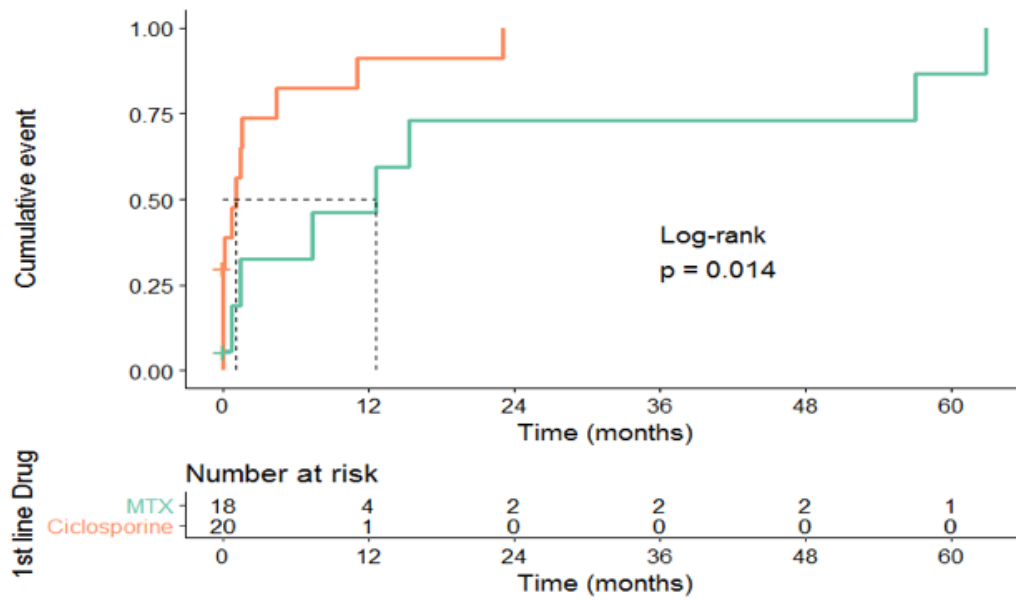

All the drugs presented in the same column belong to the same line of treatment. The height of the boxes and the thickness of the lines are proportional to the number of patients. Durations and interruptions are not represented.

Figure 3. Comparison of “drug survival” for cyclosporine (CYC) and methotrexate (MTX) as first-line immunosuppressive treatment for atopic dermatitis.

The probability of continuing the first-line immunosuppressive treatment was analysed using the Kaplan-Meier method.

Figure 4. Comparison of “post-drug survival” for cyclosporine (CYC) and methotrexate (MT) as first-line immunosuppressive treatment for atopic dermatitis.

The probability of starting the second-line immunosuppressive treatment after the discontinuation of MTX and CYC was analysed using the Kaplan-Meier method.
