**Summary**

Future climate scenarios forecast a 10 to 50% decline in rainfall in Eastern Amazonia. Altered precipitation patterns may change important ecosystem functions like decomposition through either changes in physical and chemical processes or shifts in the activity and/or composition of species. We experimentally manipulated hydroperiods (length of wet:dry cycles) in a tank bromeliad ecosystem to examine impacts on leaf litter decomposition. Gross loss of litter mass over 112 days was greatest in continuously submersed litter, lowest in continuously dry litter, and intermediate over a range of hydroperiods ranging from eight cycles of 7 wet:7 dry days to one cycle of 56 wet:56 dry days. The resilience of litter mass loss to hydroperiod length is due to a shift from biologically-assisted decomposition (mostly microbial) at short wet:dry hydroperiods to physicochemical release of dissolved organic matter at longer wet:dry hydroperiods. Biologically-assisted decomposition was maximized at wet:dry hydroperiods falling within the range of ambient conditions (12-22 consecutive dry days) but then declined under prolonged wet:dry hydroperiods (28 and 56 dry days. Fungal:bacterial ratios showed a similar pattern as biologically-assisted decomposition to hydroperiod length. Our results suggest that microbial communities confer functional resilience to altered hydroperiod in tank bromeliad ecosystems. We predict a substantial decrease in biological activity relevant to decomposition under climate scenarios that increase consecutive dry days by 1.6- to 3.2-fold in our study area, whereas decreased frequency of dry periods will tend to increase the physicochemical component of decomposition.

**Keywords:** Climate change, leaf-litter decomposition, resilience, dry:wet cycles, tank-bromeliad ecosystem
Introduction

Anthropogenic climate change will increase the frequency and intensity of extreme climatic events in many parts of the world (IPCC 2013). In neotropical regions, prolonged dry seasons related to more severe El Niño Southern Oscillation events (ENSO) have been recorded since the mid-70’s (Collins 2005), while future scenarios forecast a further 10 to 50% decline in rainfall in the northern and eastern coasts of South America and in central Amazonia (IPCC 2013, Feng et al. 2013). Negative impacts of altered precipitation have been reported for the distribution, abundance and/or activity of a broad range of plants and animals (Grant et al. 2000; Gilbert et al. 2001; Itioka and Yamauti 2004; Allen et al. 2010; Dejean et al. 2011; Bonal et al. 2016), and may have consequences for the flow of energy and nutrients within ecosystems (Trzcinski et al. 2016). However, a number of biological mechanisms that operate at different levels of organization (e.g., ecological plasticity, compensatory responses among coexisting organisms, functional redundancy, metacommunity dynamics, etc.) can contribute to ecosystem resilience, that is, the stability of ecosystem functions over time despite fluctuations in environmental conditions (Gunderson 2000; Oliver et al. 2015).

Detrital decomposition is a key process in nutrient and carbon cycling on the local to global scale, supporting food webs in terrestrial and aquatic ecosystems. This biological breakdown of coarse organic matter fuels microbial and plant productivity, and returns CO₂ to the atmosphere (Gessner et al. 1999). Once chemical-physical properties of detrital substrates are accounted for, both environmental conditions (e.g., temperature and/or hydrological regimes) and the composition and activity of decomposer communities interactively affect decomposition (Gessner et al. 2010). In particular, drought-induced stress is expected to impact decomposition either through lethal or sublethal effects on microbial and metazoan decomposers (Rees et al. 2006; Ledger et al. 2013; Trzcinski et al. 2016). Because any change
in decomposition rates will alter the productivity and carbon budget of ecosystems, determining the extent to which biologically-assisted decomposition is resilient to changes in environmental regimes could improve our ability to predict the impact of climate change on ecosystems. Biologically-assisted decomposition depends on microbial and metazoan decomposers (Gessner et al. 1999, 2010), two groups of organisms that differ in their biology (e.g., growth rates) and ecology (e.g., sensitivity to drought) (Boyero et al. 2011; Shade et al. 2012). Therefore, functional resilience to altered hydrology may depend on how drought affects the abundance and relative contribution of microorganisms and metazoa in a system.

Experiments conducted in temperate systems have shown that an increase in the duration of drought adversely affects leaf litter decomposition (Langhans and Tockner 2006) whereas an increase in drought frequency has either a moderate (Langhans and Tockner 2006; Foulquier et al. 2015) or positive impact on decomposition (Battle and Golladay 2001). Resilience to drought is inherent to ecosystems that are periodically subject to hydrological resetting (e.g., Mediterranean or arid-land freshwaters), where in situ resistance traits of species ensure rapid and repeated recovery of ecological functions after disturbance (Bogan et al. 2015). In addition to biological mechanisms underlying drought effects on decomposition, physicochemical processes due to litter emersion and/or dehydration (photodegradation, fractionation, etc) may dominate the overall decomposition process, so the frequency and duration of dry periods could affect the relative importance of biological-assisted and physicochemical litter breakdown (Andersen and Nelson 2006, Austin and Vivanco 2006). Little is known however of the extent to which microbial and/or faunal components of tropical food webs mediate ecosystem resilience to drought. Fungi and bacteria are probably the most influential decomposers in neotropical ecosystems (Boyero et al. 2011), but they play different roles during the decomposition process (Strickland and Rousk 2010). Changes
in fungal:bacterial dominance could thus affect decomposition rates, but we know little of hydrological thresholds beyond contemporary climate patterns that would trigger such changes in microorganism dominance. In soil microbial communities, fungi are less sensitive to changes in moisture than bacteria, making them more resilient to hydrological changes. Furthermore, higher fungal:bacterial ratios were associated to higher decomposition efficiency (Pascoal and Cassio 2004; Strickland and Rousk 2010; Foulquier et al., 2015; Malik et al. 2016). Changes in drought intensity and/or frequency could also adversely affect decomposition either through declines of invertebrate populations (Ledger et al. 2013), or through sublethal effects altering invertebrate per capita functions (Trzcinski et al. 2016).

Hence, while models that link environmental change, community structure and ecosystem functions are needed to predict ecosystem resilience to drought, disentangling the contribution of microorganisms and invertebrates to litter decomposition across gradients of hydrological disturbance could improve our ability to predict the impact of environmental change on ecosystems, and, more importantly, tipping points for a particular ecosystem process.

Manipulating hydrology at the whole-ecosystem level with sufficient replication is often impractical. Experimental mesocosms can be replicated at will, with only space and/or budget limitations restriction, but are criticized for their lack of realism (Stewart et al. 2013). Tank bromeliads (Bromeliaceae) are increasingly used as model ecosystems to test ecological hypotheses (Srivastava et al. 2004) because they are small in size, can be exhaustively sampled, and contain multiple trophic levels and functional feeding groups. The water-filled rosettes of tank bromeliads form small, highly replicated freshwater systems. The interlocking leaves collect rainwater (up to 4-5 liters) and incoming detritus (mostly leaf litter) that support a microbial and faunal food web (Brouard et al. 2012). As in other freshwater systems, fungi, bacteria and invertebrate shredders break down the coarse detritus into fine particles, which
are then further processed by invertebrate collectors and filterers, bacteria, and other heterotrophic microorganisms (i.e., protozoa, micrometazoa; Kitching 2009). Because their hydrology is sensitive to short and long-term fluctuations in precipitation (Zotz and Thomas 1999), tank bromeliads and their biota have been considered a suitable model to test the effects of a range of drought regimes on leaf litter decomposition in a neotropical environment (Trzcinski et al. 2016).

Neotropical ecosystems may undergo larger shifts in ecosystem functions than their temperate counterparts, because their species have narrower physiological tolerances for climatic variation (Tewksbury et al. 2008). However, the lack of empirical evidence on how drought affects community-mediated processes in neotropical ecosystems hinders our ability to predict how these ecosystems will respond to future changes, and more importantly, the extent to which ecosystem functions show resilience to altered hydrology. Our study was conducted in French Guiana which is part of the Guiana Shield in eastern Amazonia, where the intensification of the tropical Atlantic north-south sea surface temperature (SST) gradient is expected to enhance the duration and intensity of dry seasons (Malhi et al. 2008). In a field experiment conducted in tank bromeliads, we subjected leaf litter to a hydrological gradient of wet:dry hydroperiods (7 wet:7 dry to 56 wet: 56 dry days) over 112 days, and tested the subsequent effects on litter mass loss depending on the associated biota (microorganisms only vs. microorganisms and invertebrates). We analysed the responses of the gross (physicochemical + biological) and biologically-assisted decomposition to this gradient, and the extent to which decomposition shows resilience to recurrent drought. Specifically, we tested the following predictions: (i) assuming that climate history has shaped the functional response of current communities (Strickland et al. 2015), only drought intensities that exceed ambient ranges should trigger significant shifts in ecosystem processes, towards a reduction in
mass loss rates; and (ii) assuming that microorganisms have the greatest influence on detrital decomposition in neotropical aquatic ecosystems (Bovero et al. 2011, 2015; Leroy et al. 2017), the effects of hydroperiod (frequency and intensity) on decomposition should be mostly mediated by drought-induced shifts in microbial community structure.

Material and methods

Study area and bromeliad species

We conducted our experiment in French Guiana, in a lowland rainforest located near the Petit-Saut hydroelectric dam, Sinnamary (latitude: 5° 03' 43" N; longitude: 53° 02' 46" W; elevation a.s.l.: 80 m). The maximum and minimum monthly temperature averages are 33.5°C and 20.5°C respectively. The climate is moist tropical, with 3000 mm of yearly precipitation. The dry season extends between September and November, and there is another shorter and more irregular dry period in March. The maximum number of consecutive days without rainfall in a dry season in our study area is 17 ± 5.3 (annual mean ± SD, based on daily rainfall records over the past ten years (Dejean et al. 2011; Dézerald et al. 2015).

The tank bromeliad Aechmea aquilega (Salib.) Griseb. commonly occurs in the study area. Its large size allows for placement of flow-through enclosures within the wells formed by leaf axils. We selected forty-five plants with similar vegetative traits (number of leaves, height, canopy width) and maximum water volume (measured as overflow of a known water volume using a graduate cylinder) for the experiment (mean length of longest leaf 93.9 ± 22.9 cm, mean water volume of a leaf axil 113.8 ± 69.4 ml). Each plant was potted and then randomly located within the experimental forest plot. We ensured that incident radiation (the available solar radiation received by a bromeliad) above individual plants was consistent
(mean ± SD: 30.6±7.1%, calculations based on hemispherical photographs taken above each bromeliad and image processing in Gap Light Analyser software, as in Leroy et al. (2009)). The mean temperature inside plant wells was 24.4±0.6°C, and was similar to the mean air temperature (24.2 ± 0.7°C, hourly records obtained with ibutton® dataloggers).

Biological communities were homogenized six days prior to the experiment. The wells of each bromeliad were carefully sampled by pipetting out the contained water, detritus and aquatic organisms using 10-mL micropipettes with the end trimmed to widen the aperture (Jocque et al. 2010). To maximize the sampling efficiency, the water was sucked in and out three times before extracting it. The samples were pooled in a large bucket, and the overall contents were then mixed and divided by the number of plants to equalize water volumes and biological communities.

Leaf litter and flow-through enclosures

We chose two species of trees for leaf litter, *Goupia glabra* Aubl. (Goupiaceae) and *Platonia insignis* Mart. (Clusiaceae), that are among the fastest species to decompose in soil environments in French Guiana (Coq et al. 2010; Hättenschwiler and Jørgensen 2010). Both tree species are very common in French Guiana, and their leaves are frequently found as litter in bromeliad tanks. We used nets to trap dead leaves as they fell from the tree canopy. All leaves were hydrated in filtered rainwater for 24h, and then cut into strips (see below), avoiding the central vein. Leaf strips were then oven dried at 60°C for 48hrs, and weighted to the nearest 0.1 mg.

We constructed flow-through enclosures from Fischer® injection anchor sleeves, which form a rigid but perforated cylindrical plastic tube (diameter=16mm, length=85mm, mesh size=1mm). Half of the enclosures were modified by drilling additional holes (~4mm
diameter, Fig. 1) to allow invertebrate colonization and movement (hereafter, “coarse mesh”). The other half of the enclosures were covered with 80 μm Nitex® mesh (Fig. 1) to allow for water flow but prevent invertebrates access (hereafter, “fine mesh”). Each flow-through enclosure received six leaf strips, i.e. two 1x4cm and one 1x5cm strips of each litter species (Fig.1). The dry mass of a 1x4cm strip was 0.0715± 0.0119g in G. glabra, and 0.0769± 0.0126g in P. insignis (mean±SD values). The total litter biomass enclosed in the mesh tubes was similar to the natural biomass of dead leaves in bromeliads at our site (Trzcinski et al. 2016). The 1x5cm strips were used for DNA extraction to estimate the numbers of fungal and bacterial gene copies directly associated with the leaf strips (see below). The 1x4cm strips were used to estimate leaf litter mass loss. We also extracted fungal and bacterial DNA from three freshly fallen leaves from each species, to obtain reference values for fungal and bacterial gene copies that could be compared to those numbers observed in our various treatments.

Wet:dry hydroperiod treatments and set up

Based on records from the Petit Saut weather station (8km away from our field site), the number of consecutive days without rainfall in a dry season over the past 10 years ranged from 3 to 28 days. We therefore created three treatments with a number of dry days falling within this range, and an “extreme” treatment doubling the maximum number of dry days to 56 (to force the system). Our experiment thus included four hydroperiod treatments (Fig. 1) that all had a total of 56 wet days and 56 dry days but differed in the distribution of these days into consecutive wet: consecutive dry day hydroperiods (eight cycles of 7 wet:7 dry days, four cycles of 14 wet:14 dry days, two cycles of 28 wet: 28 dry days, one cycle of 56 wet:56 dry days). Wet:dry hydroperiod treatments are denoted by the number of cycles subscripted by the number of consecutive days in a wet or dry phase (i.e., 8; = eight cycles of 7 wet:7 dry days).
The four hydroperiod treatments were crossed with a “decomposer” factor which included two levels: fine mesh enclosures (microorganisms only) and coarse mesh enclosures (microorganisms + invertebrates). Each combination was replicated 18 times. We randomly assigned a given wet:dry hydroperiod treatment to a total of 36 plants. Each plant received four enclosures: one coarse- and one fine-mesh enclosures starting the experiment with the wet phase of the cycle, and another two enclosures, one of each mesh size, starting with the dry phase of the cycle (see Fig. 1). We used an additional set of 9 plants for control. Each of these 9 plant received 2 pairs of coarse- and fine-mesh enclosures containing leaf litter strips: one couple immersed for the 112 days of the experiment served as “wet control” (Fig. 1), the other couple kept in dry conditions under a rainshelter for 112 days served as “drought control” (Fig. 1). In all bromeliads, both the coarse- and fine-mesh enclosures were placed together in a large well, avoiding the central reservoir (delimited by growing young leaves) and basal senescent wells. Enclosures experiencing the wet phase of their cycle were immersed in bromeliad water. Enclosures experiencing the dry phase of their cycle were suspended just above the well, exposed to air under a small rain shelter to prevent rewetting. Shelters were made by cutting a PET 1.5L bottle of mineral water, and by using the upper part of the bottle tied to a wooden pole placed nearby the plant (see Fig. 1). Dry:wet hydroperiods were simulated by periodically raising enclosures above or lowering enclosures into the water as appropriate. This technique builds on earlier studies conducted in temperate rivers, where leaf packs in enclosures with different mesh sizes were transferred manually from aquatic to terrestrial environments to establish effects of hydroperiods and organisms on decomposition (Langhans and Tockner 2006; Bruder et al. 2011). We maintained a constant water level in all wells throughout the experiment.

Biological variables

Accepted manuscript
At the end of the field experiment, all enclosures were collected and kept in a cooler for transportation. Invertebrates were exhaustively sampled in all bromeliads by repeated pipetting, before and after rinsing the wells with diluted vinegar. Samples were preserved in 70% ethanol (final concentration) in the field. Invertebrates found in the coarse mesh enclosures were sorted in the laboratory after careful inspection of the surface of each leaf strip. All invertebrates were identified to species or morphospecies, counted and categorized by functional feeding groups *sensu* Merritt and Cummins (1996). The 1x4cm leaf strips were dried at 60°C for 48hrs and weighted to the near 0.1 mg to assess dry mass loss. The 1x5cm leaf strips were frozen prior to qPCR quantification of fungal and bacterial gene copy numbers, as described in the Appendix S1.

*Dissolved organic matter (DOM) release and leaf mass decay*

In order to evaluate the contribution of biologically-assisted decomposition to leaf mass loss, we assessed the contribution of pure physicochemical processes to litter mass loss in the laboratory (essentially DOM release due to leaching, and potentially physical fractionation due to desiccation and rewetting). We incubated 30 coarse-mesh enclosures (identical to those used in the field) consisting of 6 replicates of each of 5 treatments (156, 228, 414, 87 and a wet control, as defined earlier), in a 2L container. The container was filled with distilled water containing streptomycin and ampicillin antibiotics at a concentration of 50 mgL⁻¹ each, following the protocol and concentrations used by (Mille-Lindblom and Tranvik 2003) to prevent the development of fungi and bacteria. Each enclosure contained two 1x4cm leaf strips of each litter species, and the experiment lasted 112 days. The antibiotics were renewed every 10 days, reaching a final concentration of 0.5 g.L⁻¹. At the end of the experiment, leaf strips were dried as described above and weighed to evaluate mass loss due to pure physicochemical effects.
Data analysis

Differences in final invertebrate communities among experimental plants were tested with a permutation MANOVA test (Anderson 2001), using Bray-Curtis dissimilarities on log(x+1)-transformed invertebrate abundances.

Mass loss rate of leaf litter was used as a dependent variable to assess how leaf decomposition responded to the gradient of dry:wet cycles. We ran separate analyses for observed mass loss rate (gross decomposition) and mass loss rate corrected for DOM release (biologically-assisted decomposition). The ratio between numbers of fungal and bacterial gene copies was used as a dependent variable to test the effect of treatments on the fungus:bacteria ratio. Prior to analysis, we transformed proportions with a logit function to achieve homoscedasticity in residuals. Separate mixed effect models were ran for each leaf litter species, testing hydroperiod (4 wet:dry cycles and two controls) and mesh size (coarse or fine mesh) as fixed effects. Plant identity (individual bromeliads used for the experiment, 45 levels) and the condition of the initial phase (dry or wet) nested within plant identity were included as random effects in the models. We also explored the effect of the following covariates: maximum water volume (WV, ml), percentage incident radiation (IR), invertebrate taxonomic richness (Richness), total density of shredder-scrapers (Density_Shre ind. ml$^{-1}$), and density of each shredder-scraper taxon occurring inside plant wells (Cyphon sp. (Density_Cyph), Trentepohlia (Density_Trent) and Telmatoscopus sp. (Density_Telma).

When one factor was significant we used Tukey’s HSD test to examine pairwise differences between levels of the given factor. Additionally, to specifically test our prediction that drought intensities exceeding ambient ranges should negatively impact mass loss rates, we used a priori Helmert’s orthogonal contrasts in linear models analyzing gross decomposition data. Contrast 1 compared the mean of the dry control to the mean of all other levels of
hydropereiod factor. Contrast 2 compared the mean of the wet control to the mean of all experimental levels (1_{56}, 2_{28}, 4_{14}, 8_{7}). Contrast 3 tested the effect of dry:wet cycles >7 days, comparing the mean of the 8_{7} treatment to the mean of the three other hydroperiods (4_{14}, 2_{28}, 1_{56}). Contrast 4 tested the effect of dry:wet cycles >14 days, by comparing the mean of the 4_{14} treatment to the mean of the 2_{28} and 1_{56} treatments. Contrast 5 tested the effect of dry:wet cycles >28 days, comparing the mean of the 2_{28} treatment with the mean of treatment 1_{56}.

Model fit was evaluated graphically by exploring residuals patterns. In order to evaluate the effect of drought treatments on just biologically-assisted decomposition, we applied the same procedure to leaf litter mass losses corrected for mean physicochemical loss of litter mass for that specific hydroperiod treatment.

We used univariate ANOVAs for the DOM release experiment, with the loss of litter dry mass as the dependent variable. We ran independent ANOVA tests for each leaf litter species. Data were logit transformed and drought treatment was the independent variable with 5 levels (cycles\_days): 1_{56}, 2_{28}, 4_{14}, 8_{7} and wet control. Residuals patterns were explored graphically to assess departure from assumptions of the analysis.

All statistical analyses were performed with R software (R Core Team 2014) and the following packages: car (Fox and Weisberg 2011), nlme ver. 3.1-118 (Pinheiro et al. 2014) and vegan ver. 2.2-1 (Oksanen et al. 2015).

**Results**

*Leaf litter mass loss response to altered hydroperiod*
Intermediate mass losses were recorded in intermittent water availability treatments (i.e. wet:dry hydroperiod treatments; Fig. 2A, 2B). According to pair-wise comparisons, regardless of litter species, mass loss did not differ significantly among the four wet:dry hydroperiod treatments (156, 228, 414 and 87; Table 1), ranging from 20 to 21.7% in G. glabra and from 15.1 to 18.5% in P. insignis in these treatments. On the other hand, only for G. glabra, Helmert’s constraints pointed out a significant higher mass loss rate for 87 treatment compared with the rest of experimental hydroperiod treatments (156, 228, 414; Table 2). Mass loss of leaf litter was the lowest in drought control and the highest in wet controls. In G. glabra, the drought control had substantially lower (9.8%) mass loss and the wet control had higher (29.7%) mass loss than the wet:dry hydroperiod treatments (Fig. 2A). Similarly, in P. insignis, the drought control had significantly lower (6.6%) mass loss than the wet:dry hydroperiod treatments, whereas the wet control lost significantly more mass (18.4%) than the 156 treatment (15.1%) and the drought control (Fig. 2B).

Under antibiotic incubation in the laboratory, we recorded 4-12% mass loss over 112 days. The rate of DOM release depended on the length of the hydroperiod (G. glabra F=4.33, df=4, p=0.008 and P. insignis F=20.87, df=4, p<0.001). We estimate that such physicochemical mass loss from litter represented 20-60% of the gross mass loss recorded in our field experiment (Fig 2A, 2B). At longer hydroperiods (156 and 228), we estimated that DOM release accounted for 50-52% and 60-61% of the dry mass losses in G. glabra and P. insignis, respectively. At shorter hydroperiods (414 and 87), 32-34% and 22% of the mass loss was due to DOM release in G. glabra and P. insignis, respectively. Only in P. insignis, there was additionally a significant decrease in mass loss due to DOM release between the wet control and the 156 and 228 treatments, and between each of the two former groups and the 414 and 87 treatments. Therefore, when gross leaf litter mass losses were corrected for treatment-
specific DOM release (Fig 2C, 2D), biologically-assisted decomposition was significantly higher at shorter cycles (4\textsubscript{14} and 8\textsubscript{7}) than at longer dry periods (1\textsubscript{56} and 2\textsubscript{28}). Interestingly, the litter species differed in how continuous immersion affected biological decomposition: in \textit{G. glabra}, wet control litter had the highest rates of biologically-assisted decomposition whereas in \textit{P. insignis}, wet control litter had some of the lowest rates of biologically-assisted decomposition (Table 1, Fig 2C, 2D).

\textit{Shifts in fungal:bacterial dominance}

Absolute bacterial and fungal abundances (proxied by numbers of gene copies) were highest when invertebrates had access to leaf litter that underwent at least one dry period (2\textsubscript{28}, 4\textsubscript{14}, 8\textsubscript{7}, Fig 3A, 3B), and when invertebrates were absent in litter that was permanently immersed (1\textsubscript{56} and wet control). Fungal:bacterial ratios on the surface of the leaf strips were significantly lower in coarse mesh enclosures (microorganisms + invertebrates) than in fine mesh enclosures (microorganisms only) for \textit{G. glabra} and \textit{P. insignis} (+2.9% and +5% on average, respectively, Table 2, Fig 3C, 3D), revealing that invertebrate presence or activity decreased the dominance of fungi over bacteria. More frequent drying tended to result in higher fungal:bacterial ratios for both litter species, significantly for \textit{P. insignis} and marginally (p=0.06) in \textit{G. glabra} (Table 2). Regardless of the leaf litter species, the interaction between wet:dry hydroperiod treatment and mesh size had no significant effect on litter mass loss and fungal:bacterial ratio (Table 2). Other covariates were not significant and were thus removed from the analyses (results not shown).

\textit{Contribution of invertebrates to leaf litter mass loss}
At the end of the experiment, invertebrate communities did not differ between bromeliads used for the six manipulation types (dry control, wet control, and each of the four drought treatments; MANOVA PseudoF= 1.36, df=4, p=0.1). We sorted a total number of 10,301 invertebrates including: oligochaetes (*Aulophorus superterrenus*, 54.8% of the total abundance), dipterans (*Culex* sp. 21.1%, Chironomini 5% and Tanyponidae 3.5%), ostracods (*Elpidium bromeliarium* 7%) and odonates (unidentified Coenagrionidae, 3%). The dominant functional feeding groups were gathering-collectors (>90%) and predators (6.6%). Shredders (*Trentepohlia* sp. and *Telmatoscopus* sp. dipterans) and scrapers (*Cyphon* sp. coleopteran) only accounted for 1.3% of the total abundance.

Biologically-assisted decomposition in drought treatments and controls was essentially due to microbial activities. In *G. glabra* leaves, the increase of decomposition rate due to invertebrates was 1.5% only (Table 1, Fig 2A). For *P. insignis*, there was no difference in leaf litter mass loss between fine mesh and coarse mesh enclosures. Gross mass loss correlated significantly and positively with densities of *Trentepohlia* sp. (shredder) and *Cyphon* sp. (scraper) for both litter species, whereas biologically-assisted mass loss correlated significantly with densities of *Trentepohlia* sp. and *Cyphon* sp. for *G. glabra* and only with *Cyphon* sp. for *P. insignis* (Table 1).

**Discussion**

Whilst water availability and precipitation are the main factors controlling decomposition in tropical forests in general (Powers et al. 2009), future climate scenarios predict an increase in the frequency of dry episodes and the intensity of dry seasons in eastern Amazonia, including the Guiana Shield (IPCC, 2013). In addition to direct effects on species’ metabolism and activity, environmental change causing significant shifts in community
functional structure and resilience capability could precipitate abrupt changes in ecosystem functions (MacDougall et al. 2013). In our experiment, we did not reach a sharp decline in decomposition, although we simulated recurrent 7 to 56 days-long dry periods, i.e. up to three-times the maximum number of consecutive days without rainfall under ambient climate (17 days on average). Even if bromeliad tanks do not dry out immediately in the absence of rainfall, water level decreases quickly over consecutive days without rain, progressively exposing the leaf litter to the air from its upper to its lower parts. Our results suggest that co-occurring physicochemical and biological decomposition processes have opposite responses to drought, likely hindering our ability to detect hydrological thresholds that trigger significant alterations in functions sustained by biological communities. Within the range of simulated hydroperiods, microbial decomposition was maximized at short hydroperiods falling within the range of current ambient conditions (7-14 dry days), but then declined significantly under prolonged dry periods (28 and 56 days), together with a significant decrease in fungal:bacterial ratios. If climate has shaped the current functional responses of communities to hydrological changes, our result suggest that an ecosystem process such as biological decomposition of leaf litter would currently be close to its 'functional optimum' in the study area (Wallestein and Hall 2012).

The resilience of ecosystem functions to altered hydrology theoretically relies on the capability of influential community components to withstand perturbations (Oliver et al. 2015). Here, we manipulated litter and the microorganisms and invertebrates that colonize leaf packs to break down the dead leaves, and our results point to a major role for microorganisms in the decomposition process. Invertebrate shredders are scarce in most tropical aquatic ecosystems (Boyero et al. 2011), and this is particularly true of freshwaters of French Guiana in general (Dedieu et al. 2016). Compared to other Neotropical regions,
shredder density and biomass is particularly low in tank bromeliads of French Guiana (Brouard et al. 2012), so whatever their resistance to altered hydroperiod they likely play a minor role in ecosystem resilience (Leroy et al. 2017). We manipulated only the hydrated state of the flow-through enclosures, by raising or lowering them. Therefore, the aquatic bacteria, fungi and invertebrates that colonized the leaf packs had to resist and recover (or eventually dried out). It is however likely that, under natural drought events, terrestrial macroinvertebrates would be able to colonize the leaf packs and continue decomposition in the absence of water. That said, the low direct contribution of aquatic shredders and scrapers to decomposition suggest that the main effect of invertebrates is through indirect effects on microorganisms. The numbers of gene copies for bacteria and fungi were higher in coarse mesh enclosures for the treatments alternating wet and dry phases. Invertebrates also reduced the proportion of fungi over bacteria in both litter species, a pattern consistent with increased litter palatability (Wymore et al. 2013). It may be that invertebrates, by fragmenting larger detrital particles (Gessner et al. 1999), enhances bacterial colonization and therefore litter mass loss. This indirect effect was however only significant for _G. glabra_, the most palatable litter.

Microbial communities, which had the greatest biological influence on decomposition adapt rapidly to fluctuating water availability (Bouskill et al. 2013). Microbial communities are notably highly diversified, so functional redundancy could buffer adverse effects of environmental changes on ecological processes (Allison and Martiny 2008). Fungal assemblages respond rapidly to rewetting (Fierer et al. 2003), and bacteria buffer hydric stress by exuding polysaccharides to form biofilms. Furthermore, dry periods can increase resistance in microbial communities by filtering out drought-sensitive species and increasing the prevalence of the drought-resistant ones, so that subsequent droughts result in functional
response close to that of non-perturbed communities (Bouskill et al. 2013). For instance, an increase in the production of hydrolytic enzymes responsible for the breakdown of complex organic C compounds (thus enhancing decomposition) was observed by Bouskill et al. (2016) in samples subjected to repeated drought perturbation. Dry-wet cycles increase litter decomposition through cell wall damage, but also through hydrolysis of cellulose and related compounds (Taylor and Parkinson 1988; Alarcon-Gutierrez et al. 2010). Extracellular enzymatic activity is related to water content and drying-rewetting cycles increase the leaf litter capacity to retain water, thus increasing enzymatic activity. Drying-rewetting cycles enhance the lysis of dead microbial cells and the subsequent release of intra-cellular content make leaf tissues more digestible for decomposing microorganism penetration (Alarcon-Gutierrez et al. 2010; Mora-Gómez et al. 2018).

Fungi and bacteria however differ in their sensitivity to changes in hydroperiod. In our experiment, hydroperiod affected microbial community structure in terms of fungal:bacterial dominance. Short wet:dry hydroperiods (8:14 and 4:14) were characterized by higher fungi:bacteria ratios, denoting decreased bacterial growth while fungal growth remained unaffected or was boosted. These results are consistent with experiments on soil microbial communities for which drying-rewetting cycles lead to an increase in the fungal:bacterial ratio (Bapiri et al. 2010). The higher fungal activity (hence biologically-assisted decomposition) at shorter dry:wet cycles is probably related to the residual moisture in leaf packs allowing microorganisms to survive short dry periods and the facilitation due to the lysis of leaf litter tissue during repeated drying-rewetting. Our results suggest that the effects of hydroperiod on the biological fraction of the decomposition process are mediated by shifts in microbial community structure (Pesce et al. 2016).
Decomposition as a whole also has a physicochemical component, and its relative contribution (versus biologically-assisted decomposition) depended on hydroperiod. Interestingly, more frequent droughts appeared to limit DOM release, thereby masking the effects of enhanced fungal:bacterial ratio in the gross decomposition. We acknowledge that we did not measure bacterial nor fungi biomass in the antibiotic treatments conducted in the laboratory. Still, mass loss for the same wet:dry treatment differed between fine mesh enclosures in the field (microorganisms present) and laboratory experiment (microorganisms supposedly inhibited) (Fig. 2), suggesting efficient inhibition effect of antibiotics in the laboratory experiment. It is worth noting that in *P. insignis*, biologically-assisted decomposition (Fig. 2D) was even higher in the 87 and 414 drought treatments than in the wet and drought controls. Finally, decomposition rates also depend on leaf chemistry. Detailed studies of the nutrient and tannin content of *G. glabra* and *P. insignis* in French Guiana can be found in Coq et al. (2010), and Hättenschwiler and Jorgensen (2010). With the exception of phosphorus (higher P concentrations in *G. glabra*), the leaves of *G. glabra* and *P. insignis* only show slight differences in their chemistry. Assuming that nutrient concentrations are important determinants of leaf litter decomposition (Makkonen et al. 2012; García-Palacios et al. 2016), higher P concentrations in *G. glabra* could explain the slightly higher mass loss rates for this species (Fig. 1).

In conclusion, the results of our manipulative experiment predict a meaningful decrease in biological activity relevant to the decomposition processes under climate scenarios that would increase current numbers of consecutive dry days, whereas decreased frequency of dry periods will tend to increase the physicochemical component of decomposition. Apparent responses likely hide evidence for hydrological thresholds associated with the near-optimum functional efficiency of communities, indicating that the
mechanisms that underpin interactions between these biological and abiotic responses deserve further attention. Uncertainties however remain as regards community and ecosystem function resilience, because we did not further analyze shifts at microbial community composition in terms of taxonomic and functional trait diversity. Moreover, variation of leaf litter traits in relation to regional climates might influence the magnitude of biological effect on detrital mass loss (Hättenschwiler and Jørgensen 2010). It is also likely that (bio)geographic variations in invertebrate community structure (e.g., presence or absence of large-bodied invertebrate predators, density of shredders), in addition to variations of leaf litter quality will modulate functional resilience to drought through top-down or bottom-up effects on decomposers (Trzcinski et al. 2016). Further experimental study would therefore be needed to determine the extent to which species turnover and leaf traits determine hydrological thresholds relative to local, ambient climate.

FIGURE CAPTIONS

Fig. 1 (a) Three leaf strips are shown for each leaf litter species (G. glabra and P. insignis), including two 1x4cm strips for mass loss assessment and one 1x5 cm strip for DNA analysis. (b) Coarse- and fine-mesh size enclosures. (c) A couple of experimental tubes inside a bromeliad well (wet phase) and outside (dry phase). (d) Experimental schedule with each cell corresponding to one unit of 7 days.

Fig. 2 (a-b) Gross leaf litter mass loss (mean % ± SE; N=9 controls and N=18 hydroperiod treatments) for the two leaf litter species, Goupia glabra (a) and Platonia insignis (b) in coarse (dark grey) and fine (light grey) mesh enclosures. Black dots are leaf litter mass losses (mean % ± SE; N=6) due to DOM release, estimated from laboratory assays using antibiotics. Manipulations included two controls denoted by ‘Drought’ (0 days of immersion) and ‘Wet’ (112 days of immersion), and four hydroperiod treatments: one dry:wet cycle of 56:56 days (1\textsubscript{56}), two cycles of 28 days (2\textsubscript{28}), four cycles of 14 days (4\textsubscript{14}), and eight cycles of 7 days (8\textsubscript{7}). (c-d) Biologically-assisted leaf litter mass loss (mean % ± SE; N=9 Wet control and N=18 hydroperiod treatments) after correction for DOM release in G. glabra (c) and P. insignis (d) in coarse (dark grey) and fine (light grey) mesh enclosures. Bars marked with the same letter are not significantly different for Drought factor (p>0.05) according to Tukey’s HSD test.

Fig. 3 (a-b) Mean abundance of bacteria and fungi (number of gene copies ± SE; N=3) for Goupia glabra (a) and Platonia insignis (b) in coarse (dark grey) and fine (light grey) mesh enclosures. (c-d) Mean fungal:bacterial ratio (± SE; N=3) for G. glabra (c) and P. insignis (d). Mean fungal:bacterial ratio (± SE) from freshly-fallen leaves of G. glabra (0.006±0.0009) and P. insignis (0.002±0.0005), measured from 3 samples each, may serve as baseline reference. Manipulation levels included one control denoted ‘Wet’ (112 days of immersion),
and four drought treatments as in Fig. 2. Bars marked with the same letter are not significantly different for Drought factor (p>0.05) according to Tukey’s HSD test
