ABSTRACT

Reactions of the methylidyne (CH) radical with ammonia (NH₃), methylamine (CH₃NH₂), dimethylamine ((CH₃)₂NH), and trimethylamine ((CH₃)₃N), have been investigated under multiple collision conditions at 373 K and 4 Torr. The reaction products are detected using soft photoionization coupled to orthogonal acceleration time-of-flight mass spectrometry at the Advanced Light Source (ALS) synchrotron. Kinetic traces are employed to discriminate between CH reaction products and products from secondary or slower reactions. Branching ratios for isomers produced at a given mass and formed by a single reaction are obtained by fitting the observed photoionization spectra to linear combinations of pure compound spectra. The reaction of the CH radical with ammonia is found to form mainly imine, HN=CH₂, in line with an addition–elimination mechanism. The singly methyl substituted imine is detected for the CH reactions with methylamine, dimethylamine, and trimethylamine. Dimethylimine isomers are formed by the reaction of CH with dimethylamine, while trimethylimine is formed by the CH reaction with trimethylamine. Overall, the temporal profiles of the products are not consistent with the formation of amino carbene products in the reaction flow tube. In the case of the reactions with methylamine and dimethylamine, product formation is assigned to an addition–elimination mechanism similar to that proposed for the CH reaction with ammonia. However, this mechanism cannot explain the products detected by the reaction with trimethylamine. A C–H insertion pathway may become more probable as the number of methyl group increases.

1. INTRODUCTION

Ammonia and its amine derivatives are emitted as gases in the atmosphere from a variety of sources such as biomass burning, vegetation, combustion, as well as industry.^{1,2} These nitrogen-containing molecules are of special interest in combustion environments where they impact the oxidation and ignition of hydrocarbon fuels.^{3,4} In addition, their chemistry in reactive carbon-rich environments may play a significant role in the formation of NO_x.⁵⁻¹⁰ An improved utilization of biomass-derived nitrogen-containing compounds as fuels and a better understanding of the role of amines in combustion both require a systematic study of the chemistry of ammonia and substituted amines with combustion relevant radicals.

A large number of experiments have been performed to investigate the reaction of ammonia with radicals such as OH, CN, C₂H, and CH.¹¹⁻¹⁵ Although its reaction with the OH radical is found to be slow ($<5 \times 10^{-13} \text{ cm}^3 \text{ s}^{-1}$ from 230 K to 450 K),¹¹ ammonia reacts at a significant fraction of the collision rate with the CN,¹² C₂H,¹³ and CH radicals.¹⁴ In the case of the reactions with OH and CN, the products are predicted to mostly be NH₂ + H₂O and NH₂ + HCN.^{13,16,17} The reaction with OH proceeds directly through a HO–H–NH₂ abstraction saddle point,¹⁶ while the reaction with CN initially forms a NC–NH₃ adduct that may rearrange and dissociate to form the final products.^{13,17} The most exhaustive experimental and theoretical studies have been performed for the CH + NH₃ reaction.¹⁵ The mechanism has been assigned as addition–elimination, as further described in this introduction. Kinetic investigations with methyl-substituted amines are scarcer and data are available only for reactions with OH and CH radicals.^{14,18-22} Reactions with the OH radical proceed with a rate coefficient on the order of $1 \times 10^{-11} \text{ cm}^3 \text{ s}^{-1}$ and are predicted to occur through interaction of the OH radical with an H-atom of both the amine and methyl groups to give the abstraction products.¹⁸ Reactions of the CH radical with methyl substituted amines are fast ($>1 \times 10^{-10} \text{ cm}^3 \text{ s}^{-1}$)¹⁴ although no mechanistic information is available.

1
2
3 The methylidyne (CH) radical is an important reactive intermediate detected in
4 hydrocarbon flames (*e.g.*, methane, acetylene, ethene, ethane, propene, propane).^{13,16,23,24} Its
5 barrier-less addition toward a large number of organic and inorganic functional groups is due
6 to the carbon atom having both one singly occupied and one empty non-bonding molecular
7 orbital. Its formation in flames, along with other fuel-derived C₁-radicals (*e.g.*, CH₃, CH₂ and
8 C), occurs primarily from oxidation of small hydrocarbon compounds (*e.g.*, methane,
9 acetylene).^{17,25} Once formed, the CH radical is likely to play a role in the formation of soot
10 precursors through generation of small cyclic hydrocarbons.²³⁻²⁸ A major interest of the CH
11 radical in combustion is its ability to react with molecular nitrogen to form NCN, which is the
12 dominant source of prompt NO formation in turbulent diffusion flames.^{17,25-38} Its reaction with
13 ammonia is also included in a recent combustion model.²⁵ As fuel complexity is increased,
14 there is a need for additional data about the reaction of the CH radical with nitrogen containing
15 hydrocarbons.

33 Zabarnick *et al.*¹⁴ performed the first kinetic measurements of CH radical reactions with
34 ammonia and methyl substituted amines. They employed pulsed laser photolysis (PLP) and
35 laser-induced fluorescence (LIF) to measure rate constants for CH with NH₃, CH₃NH₂,
36 (CH₃)₂NH and (CH₃)₃N at temperatures ranging from room temperature up to 677 K. Based on
37 the observed large rate coefficients they suggested an insertion–elimination mechanism of CH
38 into one of the N-H bonds followed by rapid dissociation of the energized complex. Bocherel
39 *et al.*³⁹ measured the CH + NH₃ reaction also using a PLP–LIF technique in a supersonic flow
40 reactor between 23 and 295 K. The reaction rate coefficient is 1.37×10⁻¹⁰ cm³ s⁻¹ at 295 K and
41 displays no significant temperature (2.21×10⁻¹⁰ cm³ s⁻¹ at 23 K) or pressure dependences in
42 agreement with the study of Zabarnick *et al.*¹⁴ More recently Blitz *et al.*¹⁵ investigated the
43 products of the CH + NH₃ reaction by measuring the H-atom branching ratio using LIF. The
44 close to unity H-atom branching ratio combined with high-level (MCSCF/CASSCF)

3 calculations¹⁵ support an insertion–elimination mechanism similar to that proposed for the
4
5 reactions of CH with saturated hydrocarbons.⁴⁰ In the case of ammonia the insertion is found
6
7 to proceed first through the formation of a dative bond¹⁵ between the carbon and the nitrogen
8
9 atoms.¹⁵
10

11
12 The aim of the present study is to obtain a general mechanism for the reaction of CH
13
14 with amines. For this purpose we present a systematic investigation of the products formed by
15
16 reactions of ground state methylidyne CH($X^2\Pi$) radicals with NH₃ and three methyl
17
18 derivatives: methylamine (MA) CH₃NH₂, dimethylamine (DA) (CH₃)₂NH, and trimethylamine
19
20 (TA) (CH₃)₃N. To probe the reaction products, experiments are performed in a flow reactor
21
22 under thermal conditions (373 K and 4 Torr) at the Advanced Light Source (ALS) synchrotron
23
24 of Lawrence Berkeley National Laboratory (LBNL). Products sampled from the flow are
25
26 detected using tunable vacuum ultraviolet (VUV) photoionization and time-of-flight mass
27
28 spectrometry. Kinetic traces and photoionization spectra supported by thermodynamic and
29
30 Franck–Condon factor calculations of the species have been used to infer the primary products
31
32 of the reactions.
33
34
35
36

37 38 **2. EXPERIMENTAL PROCEDURE**

39
40 The experiments are performed in a slow flow reactor coupled to a tunable VUV
41
42 photoionization orthogonal acceleration time-of-flight mass spectrometer. A detailed
43
44 description of the apparatus has been given in the literature⁴¹⁻⁴³ and only a brief description is
45
46 given here. The reactions take place in a flow tube at 373 K and at a pressure of 4 Torr (total
47
48 density $\sim 10^{17}$ cm⁻³). The 100 sccm gas flow consists of a large excess of He with 10% nitrogen
49
50 and small amounts of CH-radical precursor (bromoform) and reagent gases (ammonia, MA,
51
52 DMA, or TMA) with typical densities of $\sim 10^{13}$ cm⁻³ and $\sim 10^{14}$ cm⁻³ respectively. The
53
54 bromoform (CHBr₃) is placed in a glass vessel and its vapor carried into the main carrier gas
55
56 flow by bubbling a controlled flow of He through the liquid. The purities of gases are:
57
58
59
60

1
2
3 bromoform (99%), CDBr_3 ($\geq 99\%$, ≥ 99.5 atom % D), NH_3 ($\geq 99.9\%$), CH_3NH_2 ($\geq 99\%$),
4
5
6 $(\text{CH}_3)_2\text{NH}$ ($\geq 99\%$), $(\text{CH}_3)_3\text{N}$ ($\geq 99\%$).
7

8 CH radicals are generated by excimer laser photolysis at 248 nm with a 4 Hz repetition
9
10 rate. The laser power output is typically 266 mJ per pulse for a 20 ns pulse duration, with a
11
12 photolysis fluence inside the flow tube of $\sim 20\text{--}50$ mJ cm^{-2} . Photodissociation occurs via
13
14 successive absorption of photons eliminating multiple halogen atoms leading to CH number
15
16 density of about 2.5×10^{10} cm^{-3} in the reaction flow.^{44,45}
17
18
19

20 The gas mixture is sampled through a pinhole halfway down the flow tube into a high-
21
22 vacuum chamber. A skimmer generates a molecular beam into the ionization chamber where
23
24 species are ionized by the quasi-continuous tunable VUV synchrotron radiation of the ALS.
25
26 The formed ions are detected through time-of-flight mass spectrometry by recording their
27
28 arrival time with respect to the extraction pulse and laser pulse. The setup leads to complete
29
30 time- and energy-resolved mass spectra by averaging 200-500 laser pulses for each ionizing
31
32 photon energy. The photoionization spectra are obtained from three independent data sets,
33
34 averaged and integrated, over the mass-to-charge ratio and time window of interest. In the
35
36 following sections a time window up to 80 ms was interrogated after the laser pulse. Mass
37
38 spectra, kinetic time traces, and photoionization spectra are corrected for pre-photolysis signals
39
40 by subtracting the average ion counts in a 20 ms time window before the laser pulse. Having
41
42 subtracted this time-independent signal, the data in the figures represents the change of signals
43
44 as a result of the reactive species created by the laser pulse. Positive signals represent species
45
46 created because of the laser pulse, whereas negative signals correspond to species that are
47
48 depleted following irradiation. Finally, all signals are normalized to variations in VUV photon
49
50 flux that is monitored using a calibrated photodiode.

3. COMPUTATIONAL METHODS

Electronic structure calculations of neutral species and their cations leading to their optimized geometries have been performed using the Gaussian09 package with the B3LYP/CBSB7 method. Details about the calculations have been discussed elsewhere.^{41,42,46,47} Heats of reaction, and adiabatic and vertical ionization energies, are calculated using the CBS-QB3 composite method.^{48,49} Simulated Franck–Condon factors of isomer species are calculated at room temperature with the G09 package within the Franck–Condon approximation.^{44,50} Although the experiments are performed at 373 K, the higher temperature does not result in significantly different vibrational populations. The calculated Franck–Condon factors are convolved with a Gaussian response function (FWHM of 0.025 eV) and integrated in order to simulate the photoionization spectra of the species assuming that direct ionization dominates the ionization process.

Saddle points for H- and CH₃-transfer on the CH + CH₃NH₂ potential energy surface (PES) are calculated using the CBS-QB3 composite method.^{48,49} The saddle points are verified with intrinsic reaction coordinate (IRC) calculations at the B3LYP/6-31G(d) level of theory.

4. RESULTS

Under the present experimental conditions (4 Torr, 373 K, high dilution with inert gases), collisional quenching with the He (90%) and N₂ (10%) buffer gases will rapidly thermalize all the photolysis and reaction products to the temperature of the flow. Stabilization will not compete with dissociation of the reaction intermediates as long as the unimolecular dissociation occurs with a rate higher than the collision rate ($<20 \times 10^6 \text{ s}^{-1}$). All the initial reaction adducts formed by addition of the CH radicals with unsaturated hydrocarbons are expected to have lifetimes shorter or on the order of their rotational period.⁴⁰ Assuming equally fast adduct isomerization and dissociation for reactions with amines under the above experimental conditions, stabilization of these intermediates through collisional quenching is not expected

1
2
3 to be a significant process. For these reasons, performing the experiments under thermal
4 conditions provides information about the unimolecular isomerization and dissociation scheme
5 of the reaction intermediates.
6
7
8
9

10 The kinetic traces and photoionization spectra are recorded by irradiating a mixture of
11 CHBr_3 and the chosen amine in a He/N_2 mixture at 248 nm. Along with $\text{CH}(X^2\Pi, \nu=0)$,
12 bromoform photodissociation produces $\text{CH}(A^2\Delta)$, $\text{CH}(X^2\Pi, \nu=1)$, Br , HBr , CBr , CHBr , Br_2
13 and CHBr_2 . The $\text{CH}(A^2\Delta)$ population decays radiatively within few microseconds after the
14 laser pulse.⁵¹ The vibrationally excited $\text{CH}(X^2\Pi, \nu=1)$ radicals are efficiently quenched by
15 adding nitrogen to the main flow.^{28,52} The three body reaction of the $\text{CH}(X^2\Pi, \nu=0)$ radical
16 with molecular nitrogen is slow⁵³ at the pressure of the flow and is unlikely to affect the
17 observed product distributions. Reactions of CBr with small unsaturated hydrocarbons are
18 several orders of magnitude slower at the present temperature^{46,47,50,54-56} than those for reactions
19 of the CH radical.^{54,55,57,58} Similarly slow kinetics between CBr and amines would allow
20 discriminating between CBr and CH reaction products. At 248 nm the singlet CHBr carbene is
21 expected to be formed in very low concentrations compared to the CH radical.⁵⁹ Its reaction
22 with ammonia or the methyl-substituted amine reactants may form products through HBr -loss
23 at the same m/z as the CH reaction products. There are no kinetic data available for the
24 reactions of halocarbenes with amines. In the case of reactions with DMA and TMA, signals
25 are observed at m/z values corresponding to dimethyl and trimethyl substituted amines plus
26 $\text{C}^{79}\text{Br}/\text{C}^{81}\text{Br}$ isotopes. This indicates that the methyl substituted amines reacts with CBr to give
27 the stabilized adduct, or with CHBr followed by a H-loss. The detection of brominated products
28 suggests that the branching ratio for Br and/or HBr elimination is less than unity. Combined
29 with the non-detection of signal at the m/z values of the brominated radicals, this suggests that
30 the direct contribution of the CBr and CHBr reactions to signals at m/z corresponding CH
31 reaction products is therefore expected to be small.

1
2
3 Successive reactions of the primary products with remaining radicals in the flow may
4 lead to the formation of secondary products over the experimental reaction time. Because the
5 reactions of CH with ammonia and amines are very fast,¹⁴ it is possible to discriminate between
6 primary and secondary reactions by inspecting the product temporal profiles. Figure S1
7 displays typical kinetic traces obtained when irradiating a mixture of bromoform and MA in
8 helium and nitrogen. The fast rise of the signals at m/z 42, 43, and 57 indicates that these
9 products are likely to be formed by a fast reaction while the slower rise observed at m/z 58
10 suggests that the corresponding product is from a slower or secondary reaction. In this section
11 photoionization spectra are integrated over the 0–40 ms time range, whereas mass spectra
12 integrations are restricted to 0–5 ms in order to minimize contribution from secondary or
13 slower reactions. Products showing initial formation rates of less than 500 s^{-1} are assigned to
14 secondary reactions and are not discussed further.

30
31 Time- and energy-resolved mass spectra are recorded by averaging at least 500 laser shots
32 at each VUV photon energy, scanned over at least 1.5 eV with an energy step of 25 meV. Ar
33 is used in a gas filter in order to absorb harmonics of the undulator radiation. All the amines
34 used in this work have low absorption cross-sections at 248 nm ($<1 \times 10^{-19} \text{ cm}^2$ for MA and
35 DMA, $\sim 1 \times 10^{-18} \text{ cm}^2$ for TMA)⁶⁰⁻⁶² leading to negligible dissociation of MA and DMA and less
36 6% dissociation for TMA. Nonetheless, mass spectra of the NH_3 , MA, DMA were
37 systematically recorded with and without bromoform in order to confirm that no time-
38 dependent signal was observed at the masses of the expected CH + amine reaction products.
39 Although no background was recorded in the case of TMA, time resolved signal observed at
40 m/z 58 is attributed to TMA photodissociation.

60 In the following sections, isomer products are identified based on their ionization
energy and photoionization spectra. When experimental values are not available, the isomers
are identified using the CBS–QB3 calculated ionization energies displayed in Table 1. The

1
2
3 difference of ionization energies between the C₂H₅N cis and trans stereoisomers is found to be
4
5 less than 0.02 eV and the isomer identification is performed using the trans isomer. The
6
7 photoion spectra are also fit with integrated experimental or integrated calculated (Franck–
8
9 Condon factors) photoelectron spectra. The predicted spectra for individual isomers are
10
11 displayed in Figure S1 (supplementary information). The integrated photoelectron spectra⁶³ do
12
13 not distinguish between the cis and trans stereoisomers. The photoelectron spectra for the
14
15 methyl substituted imines are integrated over the first two vibronic bands of the cation⁶³ and
16
17 normalized to their maximum. Because of the large uncertainties in absolute photoionization
18
19 cross sections between the different mass channel products, the data are not used to provide
20
21 reaction product branching fractions. Nonetheless, isomeric branching ratios for a given mass
22
23 channel are estimated on the assumption that isomers have equal ionization cross sections.⁶⁴ In
24
25 the following paragraphs the displayed photoionization spectra for the individual isomers are
26
27 weighted by their branching ratios.

4.1 CH + NH₃

Two H-loss exit channels of the CH + NH₃ reaction (R1) are possible, producing the imine HN=CH₂ and the amino carbene H₂N–CH through channels R1a and R1b, respectively. The only other exothermic reaction exit channel predicted by Blitz *et al.*¹⁵ is the formation of CH₃ + NH.

Figure 1. Mass spectrum obtained by photolysis of a CHBr₃ and NH₃ mixture in helium and nitrogen integrated over the 9.8-10.6 eV photon energy and the 0–5 ms time range.

Figure 1 displays the mass spectrum obtained by photolysis of a CHBr₃ and NH₃ mixture in helium integrated over the 9.8-10.6 eV photon energy and the 0–5 ms time range. The large signal at m/z 17 is likely due to fluctuations in the ammonia signal leading to a remaining positive signal after background subtraction. The main signals are observed at m/z 29, 35, and 52. The signal at m/z 29 displays a fast rise immediately after the laser pulse, as expected for a

CH + NH₃ reaction product. The temporal profiles of m/z 35 and 52 show a sharp signal rise starting about 4 ms after the laser pulse and displaying a rapid decay over the following 5 ms. Although the origin of these two signals is undetermined, NH₃•H₂O and 2NH₃•H₂O are the only species that match the observed m/z values. The formation of these clusters at 373 K is not favorable and the observed ions are more likely to come from dissociative ionization of higher mass neutral species. Additional signals (not shown here) are observed at m/z 79, 81, 104, and 106 corresponding to Br atoms and brominated compounds. The photoion signal at m/z 104 and 106 has a fast kinetic rise and shows an ion onset at about 10.3 eV corresponding to the photoionization energy of bromoacetylene.⁶⁵ Although there is no clear pathway leading to BrCCH formation in the reaction flow, its formation does not interfere with the detection of CH + NH₃ products. From this analysis, it is concluded that only the signal at m/z 29 originates from the CH + NH₃ reaction.

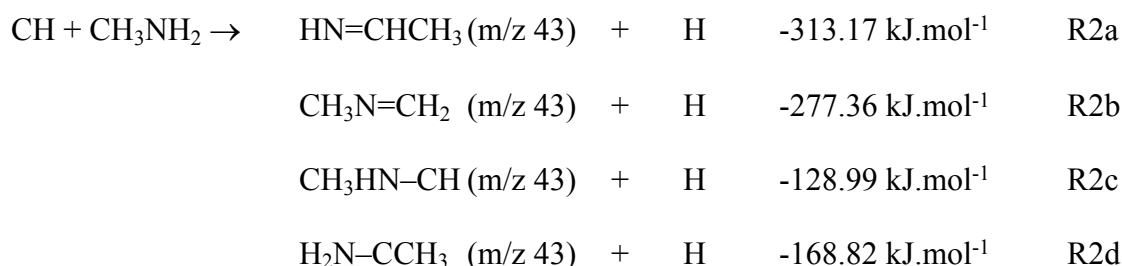

Figure 2. Photoionization spectrum of m/z 29 (open circles) obtained by photolysis of a CHBr₃ and NH₃ mixture in helium and nitrogen integrated over the 0–40 ms time range and displayed from 9.8 to 10.6 eV photon energy. The vertical line denotes the experimental ionization energy

of $\text{HN}=\text{CH}_2$.⁶³ The thick red line is the integrated experimental photoelectron spectrum of $\text{HN}=\text{CH}_2$ from Bock *et al.*⁶³

Figure 2 displays the photoionization spectrum of m/z 29 integrated over the 0–40 ms time range. The good match between the experimental data (open circles) and the integrated experimental photoelectron spectrum of $\text{HN}=\text{CH}_2$ (red thick line) from Bock *et al.*⁶³ confirms the formation of $\text{HN}=\text{CH}_2$ in the reaction flow. As displayed in Table 1 the calculated $\text{H}_2\text{N}-\text{CH}$ amino carbene ionization energy is 8.39 eV, well below that of the $\text{HN}=\text{CH}_2$ isomer. The absence of signal below 9.9 eV confirms that the amino carbene isomer $\text{H}_2\text{N}-\text{CH}$ is not formed in the reaction flow and that only R1a contributes to the reaction mechanism. Additional experiments were performed with deuterated bromoform as the radical precursor in order to provide information on isomerization pathways. The main $\text{CD} + \text{NH}_3$ product signal is observed at m/z 30 with no significant signal at m/z 29, indicating an absence of D loss from the initial adduct. The photoionization spectrum of m/z 30 is identical to that of m/z 29 from the $\text{CH} + \text{NH}_3$ reaction.

4.2 CH + CH_3NH_2

The reaction of the CH radical with MA (R2) may proceed both by H- (R2a, b, c, and d) or CH_3 -loss (R2e and f) to form imines (R2a, b, and e) or amino carbenes (R2c, d, and f) at m/z 43 and 29. The enthalpy of reaction for producing trans- vs. cis- $\text{HN}=\text{CHCH}_3$ or trans- vs. cis- $\text{CH}_3\text{HN}-\text{CH}$ stereoisomers differs by less than 3 kJ mol^{-1} ; the enthalpies of reaction given in R2a and R2c are for the trans isomers. All the exit pathways are exothermic with formation of the imines being at least 100 kJ mol^{-1} more exothermic than the amino carbenes.

Figure 3 displays the photoionization spectrum of m/z 29 (open circles) obtained by photolysis of a CHBr_3 and CH_3NH_2 mixture in helium and nitrogen integrated over the 0–40 ms time range. The thick red line is the integrated photoelectron spectrum of $\text{HN}=\text{CH}_2$ from Bock *et al.*⁶³ The good match between the experimental data and the integrated photoelectron spectrum as well as the absence of signal below 9.9 eV suggest that only the imine isomer is formed in the reaction flow.

Figure 3. Photoionization spectrum of m/z 29 (open circles) obtained by photolysis of a CHBr_3 and CH_3NH_2 mixture in helium and nitrogen integrated over the 0–40 ms time range and displayed from 9.0 to 10.3 eV photon energy. The thick red line is the integrated photoelectron spectrum of $\text{HN}=\text{CH}_2$ from Bock *et al.*⁶³

Figure 4 displays the photoion signal at m/z 15 (open circles) integrated over the 0–40 ms time range obtained by photolysis of a CHBr_3 and CH_3NH_2 mixture. The data is superposed to the

1
2
3 experimental spectrum of the methyl radical (red line).⁶⁶ The good match confirms the
4
5 formation of CH₃ radical in the reaction flow.

Figure 4. Photoion signal at m/z 15 (open circles) integrated over the 0–40 ms time range obtained by photolysis of a CHBr₃ and CH₃NH₂ mixture in helium and nitrogen displayed from 8.5 to 10.3 eV photon energy. The thick red line is the absolute spectrum (solid red line) of the methyl radical (CH₃) obtained by Savee *et al.*⁶⁶

Figure 5 displays the photoionization spectra obtained at m/z 43 recorded under the same experimental conditions as those of Figures 3 and 4. The purple solid line is a fit to the data using normalized integrated photoelectron spectra of two methylimine isomers: CH₃N=CH₂ (blue dashed line) and HN=CHCH₃ (red dotted line),⁶³ assuming equal photoionization cross sections after the first two vibronic bands. The fit to the data returns a CH₃N=CH₂:HN=CHCH₃ branching ratio of 0.9:1. The absence of onset at the ionization energy of the CH₃N=CH₂ is likely due to the poor Franck–Condon overlap between the neutral and cation vibronic ground states.

Figure 5. Photoionization spectrum at m/z 43 (open circles) obtained by photolysis of a CHBr_3 and CH_3NH_2 mixture in helium and nitrogen integrated over the 0–40 ms time range. The purple solid line is a fit to the data using the integrated photoelectron spectra of $\text{CH}_3\text{N}=\text{CH}_2$ (blue dashed line), $\text{HN}=\text{CHCH}_3$ (red dotted line) from Bock *et al.*⁶³ The best fit to the data is obtained for a $\text{CH}_3\text{N}=\text{CH}_2$: $\text{HN}=\text{CHCH}_3$ branching ratio of 0.9:1.

In Figure 5, a small ion signal is observed from 9.0 – 9.1 eV, below the energy of both imine isomers. Inspection of the kinetic traces reveals that the corresponding ions are detected only after irradiation of the flow by the laser pulse. This signal below 9.1 eV remains constant after the laser pulse, which is uncharacteristic of reactive carbene molecules. No signals are detected at the m/z corresponding to the brominated adducts, and the offset is therefore unlikely to be due to dissociative ionization of higher mass products. The constant signal offset below the energy of the methylimine isomers does not enable us to unequivocally rule out the

formation of the amino carbene isomers, but should not affect the methylimine branching ratios.

4.3 CH + (CH₃)₂NH

The reaction of the CH radical with dimethyl amine may lead to a total of 8 exothermic exit channels, through H-loss (R3a, a' b, c, and d) and CH₃-loss (R3e, f, g, and h). The enthalpy in R3e is for the trans isomer. As for the reaction with MA, formation of the methyl amino carbenes (R3c, d, g, and h) is found to be less thermodynamically favorable by at least 100 kJ.mol⁻¹.

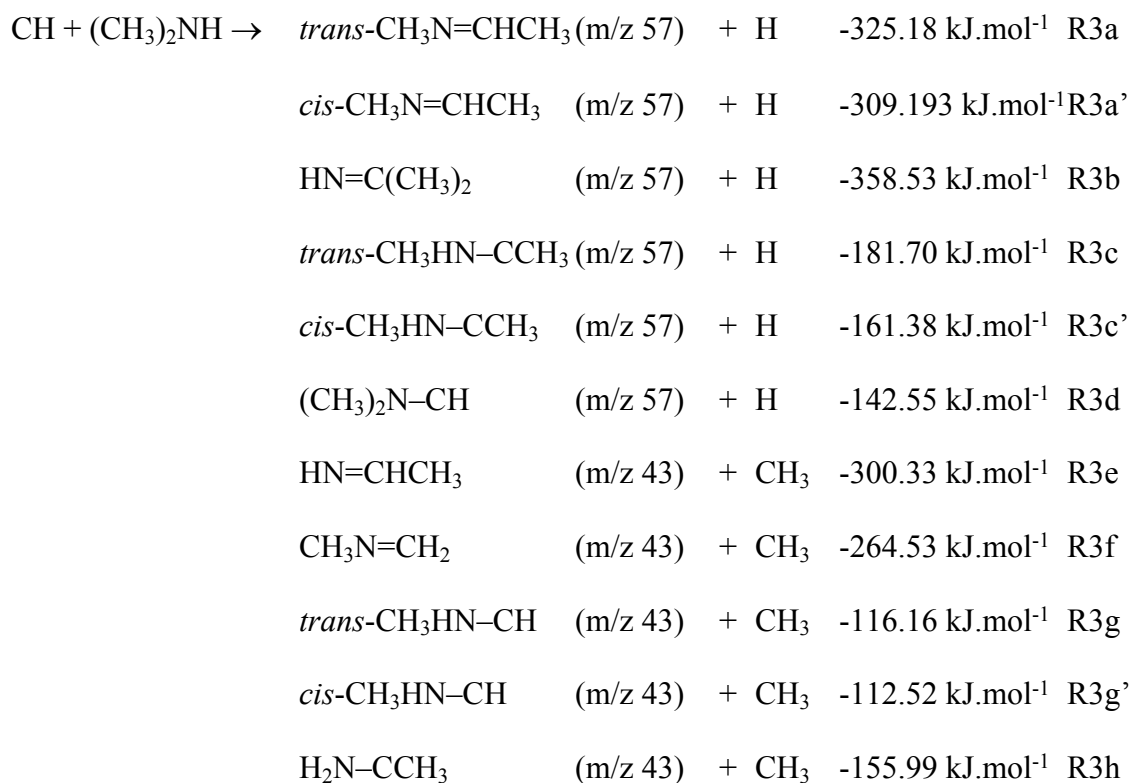

Figure 6 displays the mass spectrum obtained by photolysis of a CHBr₃ and (CH₃)₂NH mixture in helium and nitrogen integrated over the 8.5-10.6 eV photon energy and the 0–5 ms time range. The main signals are detected at m/z 15, 42, 43, 57 and 58. The signal at m/z 58 increases more slowly (400 s⁻¹) than the other signals and is likely not a direct product of the CH + DMA reaction. The photoion spectrum of m/z 42 shows an ionization onset at ~9.7 eV with a photoionization spectrum characteristic of propene (C₃H₆).

Figure 6. Mass spectrum obtained by photolysis of a CHBr_3 and $(\text{CH}_3)_2\text{NH}$ mixture in helium and nitrogen integrated over the 8.5-10.6 eV photon energy and the 0–5 ms time range.

Figure 7 displays the photoion signal at m/z 43 (open circles) integrated over the 0–40 ms time range from the same experiment. The purple solid line is a fit to the data using the integrated photoelectron spectra of $\text{CH}_3\text{N}=\text{CH}_2$ (blue dashed line) and $\text{HN}=\text{CHCH}_3$ (red dotted line) from Bock *et al.*⁶³ The best fit to the data is obtained for a $\text{CH}_3\text{N}=\text{CH}_2:\text{HN}=\text{CHCH}_3$ ratio of 0.7:1. No ion signal is detected at low energy, suggesting that no methyl amino carbene isomers are formed. The expected mass 43 co-product, the methyl radical, is detected at m/z 15 with a photoionization spectrum identical to that displayed in Figure 4.

Figure 7. Photoionization spectrum at m/z 43 (open circles) obtained by photolysis of a CHBr_3 and $(\text{CH}_3)_2\text{NH}$ mixture in helium and nitrogen integrated over the 0–40 ms time. The purple solid line is a fit to the data using the integrated photoelectron spectra of $\text{CH}_3\text{N}=\text{CH}_2$ (blue dashed line) and $\text{HN}=\text{CHCH}_3$ (red dotted line) from Bock *et al.*⁶³ The best fit to the data is obtained for a $\text{CH}_3\text{N}=\text{CH}_2:\text{HN}=\text{CHCH}_3$ branching ratio of 0.7:1.

Figure 8 displays the photoionization spectrum at m/z 57 (open circles) recorded under the same experimental conditions as those of Figure 6 and 7. The purple solid line is a fit to the data using the integrated photoelectron spectra of $\text{HN}=\text{C}(\text{CH}_3)_2$ (red dashed line) from Bock *et al.*⁶³ as well as integrated Franck-Condon factors for the *trans*- (blue dotted line) and *cis*- (blue dotted and dashed line) $\text{CH}_3\text{N}=\text{CHCH}_3$ isomers. There is a constant signal offset below the ionization energies of the *cis* and *trans* dimethylimine stereoisomers. Although the observed signal could be attributed to the dimethyl amino-carbenes $\text{CH}_3\text{HN}-\text{CCH}_3$ and $(\text{CH}_3)_2\text{N}-\text{CH}$, the m/z 57 temporal profile below the energy of the $\text{CH}_3\text{N}=\text{CHCH}_3$ dimethylimine isomers displays a constant signal after its formation by the laser pulse. Such time-trace is unlikely for reactive carbene compounds. Signals are also detected at m/z 121/123, 122/124 and 135/137,

likely corresponding to brominated compounds. No signals are observed at m/z 136/138 or 137/139 values corresponding to the $\text{CHBr/CBr} + \text{DMA}$ reaction adducts. Dissociative ionization of singly brominated products through HBr or H loss is therefore not likely to explain the observed signal offset. Alternatively, the offset could be due to dissociative ionization of CBr_2 reaction adducts through Br_2 loss. The best fit to the data using a constant offset before the ionization energy of the $\text{CH}_3\text{N}=\text{CHCH}_3$ dimethylimine isomers returns a $\text{trans-CH}_3\text{N}=\text{CHCH}_3$: $\text{cis-CH}_3\text{N}=\text{CHCH}_3$: $\text{HN}=\text{C}(\text{CH}_3)_2$ of 1:0.2:0.8.

Figure 8. Photoion signal at m/z 57 (open circles) obtained by photolysis of a CHBr_3 and $(\text{CH}_3)_2\text{NH}$ mixture in helium and nitrogen integrated over the 0–40 ms time range and displayed from 7.8 to 10.2 eV photon energy. The purple solid line is a fit to the data using the integrated photoelectron spectra of $\text{HN}=\text{C}(\text{CH}_3)_2$ (red dashed line) as well as the trans- (blue dotted line) and cis- (blue dotted and dashed line) $\text{CH}_3\text{N}=\text{CHCH}_3$. The best fit to the data is obtained for a branching ratio $\text{trans-CH}_3\text{N}=\text{CHCH}_3$: $\text{cis-CH}_3\text{N}=\text{CHCH}_3$: $\text{HN}=\text{C}(\text{CH}_3)_2$ of 1:0.2:0.8.

4.4 CH + (CH₃)₃N

The 6 most likely exit channels for the CH reaction with TMA are formation of the fully methyl substituted imine and amino carbene, detected at m/z 71 (R4a, and b), as well as the dimethylimines (R4c, c' and d) and dimethyl amino carbenes (R4e and f) at m/z 57. The enthalpies in R4g and R4i are for the trans isomers. Formation of the methyl substituted imines or amino carbene, detected at m/z 43, by loss of a C₂H₅ radical are also exothermic.

Figure 9. Mass spectrum obtained by photolysis of a CHBr_3 and $(\text{CH}_3)_3\text{NH}$ mixture in helium and nitrogen integrated over the 8.2–10.3 eV photon energy and the 0–5 ms time range.

Figure 9 displays the mass spectrum obtained by photolysis of a CHBr_3 and $(\text{CH}_3)_3\text{N}$ mixture integrated over the 8.2–10.3 eV photon energy and the 0–5 ms time range. The main signals are detected at m/z 15, 43, 58, 59, and 71. Signal at m/z 59 is likely to come from the incomplete baseline subtraction of the large TMA signal. As for the reaction with DMA, signal at m/z 15 is identified as coming from ionization of the methyl radical formed in the reaction flow. Although not as prominent as for reaction R3, signal at m/z 42 is identified as propene (~ 9.7 eV). Signal at m/z 58 displays a fast kinetics and a photoionization spectrum with a lower ionization energy onset (~ 8.9 eV) than that discussed in Section 4.3 for the bromofrom/DMA mixture at the same m/z value. After a fast rise, the signal is found to decay rapidly, within 4 ms after the laser pulse, which is not consistent with the formation of a closed shell molecule

1
2
3 from the CH + TMA reaction. In this case the signal observed at m/z 58 could come from the
4
5 dissociative ionization of a higher-mass radical species or direct photodissociation of TMA.
6

7
8 The photoionization spectrum recorded at m/z 43 for TMA and bromoform is similar to
9
10 those recorded at the same m/z for DMA and bromoform and suggests the formation of
11
12 $\text{CH}_3\text{N}=\text{CH}_2$. No signal is detected at m/z 29 for the expected C_2H_5 coproduct. In the case of
13
14 the bromoform/TMA mixture, there is a very small signal at m/z 57 (Figure 9), representing
15
16 less than 10% of the sum of all the signals at m/z 43, 57 and 71. Its photoionization spectrum
17
18 is similar to that displayed in in Figure 8 (open circles). The good match between the two
19
20 experimental photoion spectra confirms formation of the dimethylimine isomers in the flow,
21
22 although with a much lower fraction than for the CH + DMA reaction.
23
24

25
26 Figure 10 displays photoionization spectrum of m/z 71 (open circles) recorded under
27
28 the same experimental conditions as Figures 9. A large signal offset is observed below 8.5 eV.
29
30 As for the reaction with MA and DMA, the temporal profile of the ions detected at low energy
31
32 is constant after their formation upon irradiation by the laser pulse. In the case of reaction with
33
34 TMA, signals are detected at m/z 150/152 as well as 151/153 possibly corresponding to the
35
36 CHBr/CBr reaction adducts or products. Dissociative ionization of these larger mass molecule
37
38 may contribute to the observed large signal. The lack of time dependence of the low energy
39
40 m/z 71 suggests that the reactive trimethyl amino carbene isomers are not contributing
41
42 significantly to the CH + TMA reaction products. Including a constant offset, the
43
44 photoionization spectrum in Figure 10 is consistent with the formation of the $\text{CH}_3\text{N}=\text{C}(\text{CH}_3)_2$
45
46 isomer.

5. DISCUSSION

5.1 Reaction mechanisms

The reaction of the CH radical with NH_3 has been studied both experimentally and theoretically.¹⁵ The MCSCF/CASSCF PES reveals that the initial $\text{H}_3\text{N}-\text{CH}$ complex is formed by a Lewis acid/base-type reaction for which the nitrogen donates electrons to the CH Lewis acid. This donor–acceptor interaction results in positive and negative charges on the nitrogen and carbon atoms, respectively. A similar mechanism has been proposed for reactions of singlet carbene compounds (CH_2 , CHCl , CHF) with amines.⁶⁷ According to the $\text{CH} + \text{NH}_3$ PES,¹⁵ the dative $\text{H}_3\text{N}-\text{CH}$ complex is formed with no energy barrier leading to kinetics mainly controlled by long-range interactions. Scheme 1 displays the mechanism proposed by Blitz *et al.*¹⁵ The

1
2
3 initial $\text{H}_3\text{N}-\text{CH}$ adduct may directly dissociate to $\text{H}_2\text{N}-\text{CH} + \text{H}$ or isomerize through H-atom
4 transfer to form a more stable $\text{H}_2\text{N}-\text{CH}_2$ reaction intermediate. The most likely fate of the $\text{H}_2\text{N}-$
5 CH_2 intermediate is dissociation to $\text{HN}=\text{CH}_2 + \text{H}$, either directly or through a second H-atom
6 transfer followed by H-atom loss. The detection of only $\text{HN}=\text{CH}_2$ isomer as a product of the
7 $\text{CH} + \text{NH}_3$ reaction in the present study agrees with the RRKM-ME branching ratios calculated
8 on the PES by Blitz et al.¹⁵ in which the H-loss from the initial $\text{H}_3\text{N}-\text{CH}$ complex is predicted
9 not to be a competitive channel.
10
11
12
13
14
15
16
17
18

38 Scheme 1
39

40
41 The only channel leading to the imine $\text{HN}=\text{CH}_2$ through elimination of the hydrogen
42 atom initially on the carbon atom involves two successive H-transfers from the nitrogen atom
43 to the carbon atom to form the $\text{HN}-\text{CH}_3$ intermediate. In the case of the $\text{CD} + \text{NH}_3$ reaction,
44 assuming that the deuteration has no effect on the unimolecular dissociation rate, dissociation
45 of the $\text{HN}-\text{CH}_2\text{D}$ intermediate would lead to a 2:1 ratio for $\text{HN}=\text{CHD}:\text{HN}=\text{CH}_2$. The detection
46 of mainly m/z 30 from the $\text{CD} + \text{NH}_3$ reaction suggests that the second H transfer does not
47 compete with the direct dissociation of the $\text{H}_2\text{N}-\text{CHD}$ intermediate. The good agreement
48 between the present work and the RRKM-ME performed on the high-level PES supports the
49 dative-bond mechanism proposed by Blitz et al. for the $\text{CH} + \text{NH}_3$ reaction.
50
51
52
53
54
55
56
57
58
59
60

Although there is no theoretical information about the $\text{CH} + \text{NH}_2\text{CH}_3$ PES, Zabarnick *et al.*¹⁴ suggest that the reaction proceeds through insertion of the CH radical into N–H or C–H bonds followed by a rapid decomposition of the reaction intermediates. Zabarnick *et al.* proposed these mechanisms based on the comparison of the measured reaction rate coefficients with those of the $\text{CH} + \text{NH}_3$ and $\text{CH} + \text{C}_2\text{H}_6$ reactions. In view of the PES calculated for the $\text{CH} + \text{NH}_3$,¹⁵ as well as the proposed mechanism for CH_2 , CHF, and CHCl singlet carbene with MA,⁶⁷ it is likely that the reaction may also proceed through the formation of a dative intermediate. Direct insertion into a C–H bond of the methyl group is likely to be a minor entrance channel as observed for unsaturated hydrocarbons.⁴⁰

Scheme 2

Scheme 2 displays a proposed mechanism for the $\text{CH} + \text{CH}_3\text{NH}_2$ reaction starting from the formation of the dative $\text{CH}_3\text{H}_2\text{N}-\text{CH}$ intermediate. Bold arrows correspond to observed channels. The detection of m/z 15, 29, and 43 supports the fact that the reaction proceeds

1
2
3 through both H- and CH₃-loss. We have no evidence to support direct dissociation of the
4 CH₃NH₂-CH dative adduct by H-loss to form the CH₃HN-CH methyl amino carbene at m/z
5 43 or CH₃-loss to form the H₂N-CH isomer at m/z 29. The dative intermediate is therefore
6
7 more likely to isomerize through either H- or CH₃-transfer to give CH₃HN-CH₂ and/or H₂N-
8 CHCH₃ intermediates. The so-formed CH₃HN-CH₂ isomer can lose either a H atom or a CH₃
9
10 group to give the detected CH₃N=CH₂ and HN=CH₂ final imine products. The H₂N-CHCH₃
11
12 intermediate resulting from the CH₃ transfer can lose one of the two H-atoms on the nitrogen
13
14 to form the cis or trans HN=CHCH₃ imines or the H-atom initially on the carbon atom of the
15
16 CH radical to form the H₂N-CCH₃ amino carbene. Loss of the methyl group on the carbon
17
18 atom leads to the H₂N-CH amino carbene. We have no evidence of the H₂N-CH and H₂N-
19
20 CHCH₃ amino carbene in the reaction flow.
21
22
23
24
25
26
27
28

29 The 0.9:1 branching ratio for CH₃N=CH₂:HN=CHCH₃ at m/z 43 (Figure 5) suggests
30 that the CH₃-transfer may compete with the H-transfer following the formation of the initial
31
32 dative adduct. In recent literature, methyl-group transfers have not been necessary to explain
33
34 the observed reaction products from a CH reaction with saturated or unsaturated
35
36 hydrocarbons.⁴⁰ In order to gain additional knowledge about the likelihood of the methyl-group
37
38 transfer, the saddle points for the H- and CH₃-transfers from the CH₃H₂N-CH intermediate
39
40 have been calculated at the CBS-QB3 level of theory. Figure 11 displays the energetics for the
41
42 initial reaction adduct, the two isomers resulting from the H- and CH₃-transfer, as well as the
43
44 corresponding saddle points. All the energies are calculated relatively to that of the reactants.
45
46 At this level of theory the saddle point for the H-transfer is found to be below that of the
47
48 reactants while that for the CH₃-transfer is 17.1 kJ.mol⁻¹ above that of CH + CH₃NH₂.

53
54
55
56
57
58
59
60

Figure 11. C₂H₆N stationary points calculated using the CBS–QB3 method.

Estimates for absolute uncertainty of the CBS–QB3 method⁶⁸ make it unlikely that the CBS–QB3 saddle point energy for methyl transfer lies below the reactant energy. Although the CBS–QB3 method has been shown not to be appropriate to calculate the energy of a dative interaction,^{68,69} the relative energies of the two saddle points displayed in Figure 11 show that the CH₃ transfer is energetically less favorable than the H-transfer. As suggested for B–N dative bonds, the MP2 method and higher level methods may be more appropriate for such studies.⁶⁹ The detection of HN=CHCH₃ from the CH + CH₃NH₂ reaction may be explained by a lowering of the CH₃-transfer transition state below that of the reactants due to the dative interaction. Alternatively, direct insertion of the CH radical into the N–C or a methyl C–H bond could become a competitive entrance channel. Scheme 3 displays a possible mechanism for radical insertion into a C–H bond requiring only one H-atom transfer (and no CH₃ transfer) to form the H₂N–CHCH₃ intermediate. Loss of a H-atom from the nitrogen forms the cis- or trans-

1
2
3 methylimine isomers. It is possible that such a mechanism become more favorable as the
4
5 number of methyl groups on the reactant amine increases. Further calculations at a higher level
6
7 of theory are required in order to discriminate between the direct insertion and dative
8
9 intermediate mechanisms for this reaction.

Scheme 3

The CH + (CH₃)₂NH reaction may be discussed using a similar dative mechanism as those described for the CH + NH₃ and CH + CH₃NH₂ reactions. As for the reaction of CH with MA, the product detection study does not allow differentiating between a direct N–H/N–C insertion and an addition/isomerization entrance channel. The non-detection of the reactive (CH₃)₂N–CH and CH₃HN–CH amino carbenes suggests that direct decomposition of the (CH₃)₂HN–CH dative adduct through H- or CH₃-loss is not a competitive channel. Scheme 4 shows the proposed mechanism based on the isomerization of a datively bond intermediate to form imine products. Bold arrows correspond to observed channels. Pathways to amino carbene compounds are not shown.

Scheme 4

The initial $(\text{CH}_3)_2\text{HN}-\text{CH}$ dative intermediate may isomerize to $(\text{CH}_3)_2\text{N}-\text{CH}_2$ or $\text{CH}_3\text{HN}-\text{CHCH}_3$ through H- or CH_3 -transfers, respectively. The detection of $\text{CH}_3\text{N}=\text{CH}_2$ and $\text{HN}=\text{CHCH}_3$ may be explained by loss of a methyl group on the nitrogen atom from the H-transfer and the CH_3 -transfer isomers. Loss of a H atom from the $\text{CH}_3\text{HN}-\text{CHCH}_3$ isomer leads to the observed $\text{CH}_3\text{N}=\text{CHCH}_3$ product at m/z 57. The $\text{CH}_3\text{HN}-\text{CHCH}_3$ intermediate may also be formed through a more direct C-H insertion mechanism as proposed in scheme 3 for the methyl substituted amine. The fit to the photoionization spectrum in Figure 8 suggests the detection of the $\text{HN}=\text{C}(\text{CH}_3)_2$ isomer. Its formation through the formation of the dative intermediate would require the transfer of two methyl groups from the nitrogen atom to the carbon atom to give the $\text{HN}-\text{CH}(\text{CH}_3)_2$ intermediate or one methyl group through a C-H or N-C insertion mechanism.

The main observed H- and CH_3 -loss products from the $\text{CH} + (\text{CH}_3)_3\text{N}$ reaction are $\text{CH}_3\text{N}=\text{CH}_2$ and $\text{HN}=\text{CHCH}_3$ at m/z 43 and $\text{CH}_3\text{N}=\text{C}(\text{CH}_3)_2$ at m/z 71. Isomers at m/z 57 are also detected but are a minor pathway with an overall ion signal representing only 10% of the identified reaction products. Scheme 5 displays the possible reaction pathways following isomerization of the $(\text{CH}_3)_3\text{N}-\text{CH}$ dative adduct by methyl transfer or isomerization of the C-H insertion adduct by H-transfer. Bold arrows correspond to observed channels. The minor dimethylimine channel detected at m/z 57 may be formed by methyl loss from the $(\text{CH}_3)_2\text{N}-\text{CHCH}_3$ intermediate to give $\text{CH}_3\text{N}-\text{CHCH}_3$. Formation of $\text{HN}=\text{C}(\text{CH}_3)_2$ would require a methyl group transfer and a H-transfer, which is unlikely.

Scheme 5

In scheme 5, formation of the $\text{CH}_3\text{N}=\text{C}(\text{CH}_3)_2$ isomer at $m/z \ 71$ requires the transfer of a CH_3 group from the $(\text{CH}_3)_2\text{N}-\text{CHCH}_3$ intermediate to form a $\text{CH}_3\text{N}-\text{CH}(\text{CH}_3)_2$ intermediate followed by H-loss. This mechanism is similar to the successive two-H-atom transfers predicted by Blitz *et al.*¹⁵ for the $\text{CH} + \text{NH}_3$ reaction. High-level quantum calculations and RRKM-based master equation calculations would be useful to explore these mechanisms in more detail. Formation of methylimine products by the $\text{CH} + \text{TMA}$ reaction requires the loss of an ethyl group. Although we do detect methylimines at $m/z = 43$ in this reaction, the absence of signal from the expected co-product C_2H_5 radical ($\text{IE}=8.12 \text{ eV}$)⁶⁵ in Figure 9 is puzzling.

5.2 Relevance for combustion chemistry

Prediction of NO_x formation from combustion processes is a very active subject of research, especially due to the increasing use of fuels derived from biogenic sources (*e.g.*, biomass, agricultural wastes).⁷⁰⁻⁷⁴ Biomass combustion could contribute to nitrogen conversion through the formation of nitrogenized intermediates such as HCN. Their formation may depend on the fuel structure. Accordingly, several studies have focused on flames burning nitrogenized compounds (*e.g.*, ammonia, pyrrole, pyridine).⁷⁵⁻⁸⁰ The spatial detection of nitrogen containing radicals in laminar flames of DMA, ethylamine,⁸¹ and morpholine⁸² suggests that the NH_2 radical is formed very early in the combustion process and further reacts to form HCN, CN, and NO. The mole fraction of ammonia is also found to be relatively large (6×10^{-2}) and is likely

2
3 to play a role in the formation of nitrogen reactive species and nitrogen containing
4 hydrocarbons. The reactions of ammonia with other abundant combustion radicals is therefore
5 likely to affect the formation of NH_2 radicals and ultimately NO. In the present study, the
6 abstraction channel $\text{NH}_2 + \text{CH}_2$ from the $\text{CH} + \text{NH}_3$ reaction is not detected at the temperature
7 of the flow (373 K). This product channel is calculated to be endothermic by 20.9 kJ mol^{-1}
8 (CCSD(T))¹⁵ and could become accessible at flame temperatures ($>2000 \text{ K}$). The formation of
9 the thermodynamically favorable $\text{HN}=\text{CH}_2$ may still remain a dominant pathway. Further
10 reaction of the detected imine may lead to larger nitrogen containing molecules and contribute
11 to incorporating nitrogen in large hydrocarbons such as polycyclic nitrogen containing
12 aromatic hydrocarbons.

26
27 Imine and methyl substituted imines have been detected during the combustion of
28 biomass model fuels.⁸² As for ammonia, the reaction of methyl substituted amines with the CH
29 radical may contribute to their formation and to the overall molecular growth scheme in
30 combustion. Abstraction of a H-atom from the carbon group substituent may become more
31 likely as the number of C–H bonds increase. The product detection performed in the present
32 study together with the temperature independent rate coefficient reported by Zabarnick *et al.*¹⁴
33 suggest that the addition–elimination mechanism will still play a role even at combustion-
34 relevant temperatures. The isomer resolved detection of the methyl substituted imines and their
35 proposed formation mechanisms is likely to improve the quality of the chemical models used
36 to reproduce their spatial molar fraction in flames.⁸²

50 VI. CONCLUSION

51
52 The systematic study of the reaction of the methylidyne radical with ammonia, methyl,
53 dimethyl, and trimethyl amine provides empirical evidence supporting a general reaction
54 mechanism for CH reacting with amines. The detection of mainly the imine isomer upon
55 reaction of CH with ammonia is in agreement with the mechanism proposed by Blitz *et al.*¹⁵
56
57
58
59
60

1
2
3 based on high-level calculations and RRKM-based master equation calculations. According to
4 this mechanism, the insertion of the CH radical onto a N–H bond proceeds by the initial
5 formation of a dative C–N bond. The donor–acceptor type mechanism is barrierless and is
6 likely to occur over a wide range of temperatures, including under combustion conditions.
7
8
9
10

11
12 Although no theoretical data are available for the CH reaction with methyl substituted
13 amines, a similar mechanism as that proposed for the reaction with ammonia may be employed
14 to interpret the products detected for the CH + MA, DMA, and TMA. For each reaction, the
15 detection of H- and CH₃-loss products may be explained in part through isomerization of an
16 initial dative adduct formed by the sharing of the nitrogen lone pair with the carbon atom of
17 the CH radical. Kinetic traces of the reaction products show no evidence of the formation of
18 the reactive methyl-substituted amino carbene isomers. The detection of the methylimine with
19 the methyl group on the carbon atom in the case of the CH + MA reaction suggests that the
20 transfer of a methyl group could be a competitive pathway, but our calculations show a barrier
21 well above reactant energy for this process. However, a direct insertion pathway of the CH
22 radical into a methyl C–H bond may become competitive as the number of methyl group
23 increases. Our data do not allow differentiating between a dative mechanism and direct
24 insertion, but provide evidence that the latter should be considered. In the case of the CH +
25 TMA reaction, direct insertion of the CH radical into a C–H bond would lead to a pathway
26 involving only one CH₃-transfer followed by H-loss to explain the formation of the detected
27 CH₃N=C(CH₃)₂ isomer. Methylimine isomers are detected from both the CH + DMA and CH
28 + TMA reactions. The lack of imine absolute ionization cross section does not allow to quantify
29 their branching fractions. In the case of the CH + TMA reaction formation of methylimines
30 should also produce a C₂H₅ radical, which we do not observe.

55
56 Overall the dative reaction mechanism proposed by Blitz *et al.*¹⁵ for the CH + NH₃
57 reaction as well as Ramasami *et al.*⁶⁷ for the CH₂/CHCl/CHF + CH₃NH₂ is not sufficient to
58
59
60

1
2
3 explain all the detected products and a C–H insertion mechanism is likely to become favorable
4
5 for alkyl substituted amines. Although the present studies provide valuable data for the
6
7 understanding of the reactivity of amines with the CH radical, further theoretical studies
8
9 including RRKM-based master equations on the potential energy surface and experimental
10
11 studies of photoionization cross sections are paramount toward the full understanding of the
12
13 reaction mechanism, especially about the competition between direct N–C insertion and
14
15 formation of an initial dative intermediate.
