Abstract

The field of psychology has become increasingly concerned with issues related to 87 methodology and replicability. Infancy researchers face specific challenges related to 88 replicability: high-powered studies are difficult to conduct, testing conditions vary across 89 labs, and different labs have access to different infant populations, amongst other factors. 90 Addressing these concerns, we report on a large-scale, multi-site study aimed at 1) assessing 91 the overall replicability of a single theoretically-important phenomenon and 2) examining 92 methodological, situational, cultural, and developmental moderators. We focus on infants' 93 preference for infant-directed speech (IDS) over adult-directed speech (ADS). Stimuli of 94 mothers speaking to their infants and to an adult were created using semi-naturalistic 95 laboratory-based audio recordings in North American English. Infants' relative preference for 96 IDS and ADS was assessed across 67 laboratories in North America, Europe, Australia, and 97 Asia using the three commonly-used infant discrimination methods (head-turn preference, 98 central fixation, and eve tracking). The overall meta-analytic effect size (Cohen's d) was 0.3599 [0.29 - 0.42], which was reliably above zero but smaller than the meta-analytic mean 100 computed from previous literature (0.67). The IDS preference was significantly stronger in 101 older children, in those children for whom the stimuli matched their native language and 102 dialect, and in data from labs using the head-turn preference procedure. Together these 103 findings replicate the infant-directed speech preference but suggest that its magnitude is 104 modulated by development, native language experience, and testing procedure. 105

Quantifying sources of variability in infancy research using the infant-directed speech preference

The recent focus on power, replication, and replicability has had important 111 consequences for many branches of psychology. Confidence in influential theories and classic 112 psychological experiments has been shaken by demonstrations that much of the experimental 113 literature is under-powered (Button et al., 2013), that surprisingly few empirical claims have 114 been subject to direct replication (Makel, Plucker, & Hegarty, 2012), and that the direct 115 replication attempts that do occur often fail to substantiate original findings (Open Science 116 Collaboration, 2015). As disturbing as these demonstrations may be, they have already led 117 to important positive consequences in psychology, encouraging scientific organizations, 118 journals, and researchers to work to improve the transparency and replicability of 119 psychological science. 120

To date, however, researchers in infancy have remained relatively silent on issues of 121 replicability. This silence is not because infant research is immune from the issues raised. 122 Indeed, the statistical power associated with infant psychology experiments is often unknown 123 (and presumably too low (Oakes, 2017)), and the replicability of many classic findings is 124 uncertain. Instead, one reason for the infancy field's silence is likely related to the set of 125 challenges that come with collecting and interpreting infant data – and developmental data 126 more generally. For example, it can be quite costly to test large samples of infants or to 127 replicate past experiments. Another challenge for infancy researchers is that it is often 128 difficult to interpret contradictory findings in developmental populations, given how 129 children's behavior and developmental timing varies across individuals, ages, context, 130 cultures, languages, and socioeconomic groups. While these challenges may make 131 replicability in infancy research more difficult, they do not make it any less important. 132

133

Indeed, it is of primary importance to evaluate replicability in infancy research (see

Frank et al., 2017). But how can this evaluation be done? Here we report the results of a 134 large-scale, multi-lab, pre-registered infant study. This study was inspired by the ManyLabs 135 studies (e.g., Klein et al., 2014), in which multiple laboratories attempt to replicate various 136 social and cognitive psychology studies, and moderators of study replicability are assessed 137 systematically across labs. Given the reasons discussed above, it would be prohibitively 138 difficult to examine the replicability of a large number of infant studies simultaneously. 139 Instead, we chose to focus on what developmental psychology can learn from testing a single 140 phenomenon, assessing its overall replicability, and investigating the factors moderating it. 141 As a positive side effect, this approach leads to the standardization and delineation of 142 decisions concerning data collection and analysis across a large number of labs studying 143 similar phenomena or using similar methods. For this first "ManyBabies" project, we selected 144 a finding that the field has good reason to believe is robust – namely, infants' preference for 145 infant-directed speech over adult-directed speech – and tested it in 67 labs around the world. 146 This phenomenon has the further advantage that it uses a dependent measure – looking time 147 - that is ubiquitous in infancy research. In the remainder of this Introduction, we briefly 148 review the literature on the relevance of infant-directed speech in development, and then 149 discuss our motivations and goals in studying a single developmental phenomenon at scale. 150

¹⁵¹ Infant-Directed Speech Preference

Infant-directed speech (IDS) is a descriptive term for the characteristic speech that caregivers in many cultures direct towards infants. Compared to adult-directed speech (ADS), IDS is often higher pitched, with greater pitch excursions, and shorter utterances, among other differences (Fernald et al., 1989). While caregivers across many different cultures and communities use IDS, the magnitude of the difference between IDS and ADS varies (Englund & Behne, 2006; Farran, Lee, Yoo, & Oller, 2016; Fernald et al., 1989; Newman, 2003). Nevertheless, the general acoustic pattern of IDS is readily identifiable to adult listeners (Fernald, 1989; Grieser & Kuhl, 1988; Katz, Cohn, & Moore, 1996; Kitamura
& Burnham, 2003).

A substantial literature has observed infants' preference for IDS over ADS using a 161 range of stimuli and procedures. For example, Cooper and Aslin (1990), using a contingent 162 visual-fixation auditory preference paradigm, showed that infants fixate on an unrelated 163 visual stimulus longer when hearing IDS than when hearing ADS, even as newborns. Across 164 a variety of ages and methods, other studies have also found increased attention to IDS 165 compared to ADS (Cooper & Aslin, 1994; Cooper, Abraham, Berman, & Staska, 1997; 166 Fernald, 1985; Havashi, Tamekawa, & Kiritani, 2001; Kitamura & Lam, 2009; Newman & 167 Hussain, 2006; Pegg, Werker, & McLeod, 1992; Santesso, Schmidt, & Trainor, 2007; L. Singh, 168 Morgan, & Best, 2002; Werker & McLeod, 1989). In a meta-analysis by Dunst, Gorman, and 169 Hamby (2012), which included 34 experiments, the IDS preference typically had an effect 170 size of Cohen's d = 0.67 [0.57 - 0.76] – quite a large effect size for an experiment with 171 infants (Bergmann et al., 2018). 172

The evidence suggests that IDS augments infants' attention to speakers (and 173 presumably what speakers are saying) because of highly salient acoustic qualities such as 174 frequency modulation (Cusack & Carlyon, 2003). In addition, it is hypothesized that the IDS 175 preference plays a pervasive supporting role in early language learning. For example, young 176 infants are more likely to discriminate speech sounds when they are pronounced with typical 177 IDS prosody than with ADS prosody (Karzon, 1985; Trainor & Desjardins, 2002). There are 178 also reports that infants show preferences for natural phrase structure in narratives spoken in 179 IDS but not in ADS (cf., Fernald & McRoberts, 1996; Hirsh-Pasek et al., 1987). In addition, 180 word segmentation (Thiessen, Hill, & Saffran, 2005) and word learning (Graf Estes & Hurley, 181 2013; Ma, Golinkoff, Houston, & Hirsh-Pasek, 2011) are reported to be facilitated in IDS 182 compared to ADS. Naturalistic observations confirm that the amount of speech directed to 183 US 18-month-olds (which likely bears IDS features), rather than the amount of overheard 184

speech (which is likely predominantly ADS), relates to the efficiency of word processing and 185 expressive vocabulary knowledge at 24 months (Weisleder & Fernald, 2013). Finally, infants 186 show increased neural activity to familiar words in IDS compared to ADS, and also 187 compared to unfamiliar words in either register (Zangl & Mills, 2007). From a theoretical 188 perspective, the IDS register has been claimed to trigger specialized learning mechanisms 189 (Csibra & Gergely, 2009) as well as boost social preferences and perhaps attention in general 190 (Schachner & Hannon, 2011), as it even has been reported to improve performance in 191 non-linguistic associative learning (e.g., Kaplan, Jung, Ryther, & Zarlengo-Strouse, 1996). 192

¹⁹³ The Current Study: Motivations and Goals

Despite the large body of research on infants' preference for IDS and its positive effects 194 on the processing of linguistic and non-linguistic stimuli, a number of open questions remain 195 regarding this effect. This study was designed to answer some of these IDS-specific questions 196 as well as questions about methods for assessing infants' cognition, including concerns about 197 the interaction between statistical power and developmental methodologies. We describe the 198 key questions for our study below (as well as our predictions, where applicable), in rough 199 order of decreasing specificity, highlighting methodological decisions that follow from 200 particular goals. 201

What is the magnitude of the IDS preference? First and foremost, our study serves as 202 a large-scale, precise measurement of IDS preference across a large number of labs. Based on 203 evidence summarized in a previous meta-analysis (Dunst et al., 2012), we expect that the 204 preference will be non-zero and positive. We suspect, however, that this phenomenon, like 205 many others, suffers from a file-drawer effect, in which studies with low effect sizes (or large 206 p values) often do not get published. Also, there is reason to believe that effect sizes in 207 infancy research are often incorrectly reported; for example, partial eta-squared η_p^2 is often 208 misreported as eta-squared η^2 . This confusion is likely to inflate the practical significance of 209

the findings, leading to an overestimation of the statistical magnitude and importance of
effects (Mills-Smith, Spangler, Panneton, & Fritz, 2015). Therefore, the mean effect size of
0.67 reported by Dunst et al. (2012) is likely an overestimate of the real effect size.

How does IDS preference vary across age? We could plausibly predict that, all else being equal, older infants can more effectively process ADS than younger infants, and so the attraction of IDS over ADS might attenuate with age (Newman & Hussain, 2006). On the other hand, older infants might show a stronger preference for IDS over ADS, given that older infants have had more opportunity to experience the positive social interactions that likely co-occur with IDS, including but not limited to eye contact, positive facial expressions, and interactive play.

How does IDS preference vary with linguistic experience and language community? 220 Preference for IDS might be affected by infants' language experience. Across many areas of 221 language perception, infants show a pattern of perceptual narrowing. They begin life as 222 "universal listeners" ready to acquire any language(s), but with experience gain sensitivity to 223 native language distinctions and lose sensitivity to non-native distinctions (Maurer & 224 Werker, 2014). If preference for IDS follows a similar pattern, then we predict that older 225 infants tested in their native language will show a stronger preference for IDS over ADS than 226 infants tested in a non-native language. 227

Faced with several competing concerns, we made the decision that all infants in our 228 study, regardless of native language, would be exposed to ADS and IDS stimuli in North 229 American English (NAE). This design choice had several practical advantages. Most 230 importantly, every infant was tested with the same stimulus set. Creating different stimulus 231 sets in different languages would add methodological variability across labs that would be 232 statistically indistinguishable from lab identity and language environment. Further, creating 233 a single high-quality stimulus set shared across labs would reduce the time and cost of 234 conducting the study. 235

There are both design-related advantages and drawbacks to this decision. A limitation 236 of our design is that NAE stimuli are unfamiliar to infants from other language or dialect 237 communities; thus these infants might show less interest for NAE speech overall and/or may 238 have a harder time recognizing IDS features as such when they differ from those used in their 239 native language or dialect. In fact, previous work even suggests that infants' IDS preference 240 depends on the characteristics of the type of IDS addressed to children their own age 241 (McRoberts, McDonough, & Lakusta, 2009). Although this is a relevant concern, previous 242 research has documented some IDS preference in the face of language and age mismatches 243 (McRoberts et al., 2009; Werker, Pegg, & McLeod, 1994); and corpus studies suggest that, if 244 anything, the distinction between IDS and ADS is more salient in NAE than in other 245 linguistic variants (e.g., Fernald et al., 1989; Shute, 1987). Further, although this design does 246 not allow us to disentangle the effects of stimulus language (native vs. non-native) from the 247 effects of infants' cultural background, we can explore how aspects of these factors influence 248 infants' preference for IDS. 249

After weighing these considerations, we adopted NAE stimuli to provide the maximal chance of recovering a positive effect, ensure that stimuli are not a source of variance across labs, allow comparability with previous work, and also minimize the barriers to entry (i.e., the need to create lab-specific stimuli) for each participating lab. So as to be able to assess children's language background at the group level, we also chose to focus our primary analyses on monolingual infants (a separate effort analyzed IDS preferences in bilingual children; Byers-Heinlein et al., accepted pending data collection).

We focused here on three primary methods: single screen central fixation, eye tracking, and the head-turn preference procedure (HPP). All three methods are widely used in the field of infant language acquisition, and yield measurements of preference for a given type of auditory stimulus, indexed by infants' looking to an unrelated visual stimulus. In the single screen central fixation method, infants were shown an uninformative image (a checkerboard) on a single, centrally-located monitor, while listening to either IDS or ADS, and looking time to the monitor was manually coded via a closed-circuit video camera. In the eye tracking method, infants saw a similar display, but looking times were measured automatically via a remote corneal-reflection eye tracker. In the HPP method, infants saw an attractor visual stimulus (often a flashing light bulb) appear to either their left or their right, and the duration of their head turn while IDS or ADS played was manually coded via a closed-circuit video camera (Nelson et al., 1995).

Each lab tested the same phenomenon, using the same stimuli and the same general experimental parameters (including, e.g., trial order, maximum trial length), varying only in the method of measuring preference. We thus can analyze whether this theoretically irrelevant methodological choice influences effect size, helping to guide future decision-making.

What are the effects of testing infants in multiple experiments during a single lab visit? 274 Labs vary in whether each infant visiting the lab completes a single experiment only, or 275 whether some infants participate in a second study as well. These "second session" 276 experiments are thought by some researchers to yield greater dropout rates and less reliable 277 measurements, but the existence and magnitude of a "second session" effect has not been 278 tested, to our knowledge. In our study, a number of participating labs ran the IDS 279 preference study with some infants who had already been tested on additional studies; 280 measurements from these infants can inform future lab administration practices. 281

What should our expectations be regarding replicability and statistical power in studies of infancy? Although we are only replicating a single phenomenon, the importance and assumed robustness of the IDS preference means that our study still provides data relevant to developing a more nuanced understanding of replicability and power in infancy research. Because of the large number of participating labs, data from some labs does not support an IDS preference (i.e., yields a small – or even negative – effect size when analyzed individually). Some variability is expected due to the mathematics of estimating an effect at
so many independent sites. Nonetheless, we inspect whether there is systematic variability
explained by lab effects.

In addition, by providing an unbiased estimate of effect size for an important 291 developmental phenomenon (including estimates of how that effect varies across ages, 292 language backgrounds, and tasks), this work gives a rough baseline for other scientists to use 293 when planning studies. Existing attempts to estimate the statistical power of infant 294 experiments have been contaminated by publication bias, which leads to an overestimation of 295 typical effect sizes in infant research. Such overestimates can lead subsequent studies to be 296 under-powered (expecting to see larger effects than are truly present). Though our report 297 estimates the effect for a particular developmental preference, we can compare our unbiased 298 estimate, calculated both across all three methods and for each method, to the meta-analytic 290 effect extracted from previously published studies. This calculation can provide a rough 300 estimate of the effect size inflation in general, and for each method in particular, at least for 301 this particular phenomenon. 302

How should we think about the relationships between experimental design, statistical 303 significance, and developmental change? Previous work often employs a contrast between 304 two ages to suggest that a developmental change has taken place; for example, by showing 305 that 7-month-old infants show a statistically reliable preference in a task, but 5-month-old 306 infants do not. Such a finding (the pairing of a significant difference and a non-sigificant 307 difference) is not sufficient to show a difference between two time points (Nieuwenhuis, 308 Forstmann, & Wagenmakers, 2011). Even in the case where a significant difference is found 309 between the two age groups, such a result is not sufficient to elucidate the developmental 310 pattern underlying this discrete test. By measuring how effect sizes change over age with a 311 much denser sampling approach, our data and continuous analytic approach illustrate what 312 stands to be gained with a more gradient approach to testing behavior over development. 313

314 Summary

This broad replication of IDS preferences helps to answer basic questions about the replicability of developmental psychology findings and will also provide useful benchmarks for how to design infant cognition studies going forward. Just as projects such as ManyLabs have led to important improvements in research practices in cognitive and social psychology, we hope that ManyBabies will play a similar role for developmental cognitive science.

320

Methods

321 Participation Details

Time frame. We issued an open call for labs to participate on February 2nd, 2017. Data collection began on May 1st, 2017. Data collection was scheduled to end on April 30th, 2018 (one year later). In order to allow labs to complete their sample, however, a 45 day extension was granted, and data collection officially ended on June 15th, 2018. Data collection from one laboratory extended beyond this timeframe (see below in Methods Addendum).

Age distribution. Each participating lab was asked to recruit participants in one or 328 more of four age bins: 3:0 - 6:0, 6:1 - 9:0, 9:1 - 12:0, and/or 12:1 - 15:0 months. Each lab was 329 tasked with ensuring that, for each age bin they contributed, the mean age fell close to the 330 middle of the range and the sample was distributed across the bin. We selected three-month 331 bins as a compromise, on the assumption that tighter bins would make recruitment more 332 difficult while broader bins would lead to more variability and would blur developmental 333 trends (i.e., by introducing possible interactions between age and lab-specific effects, for 334 instance, if a particular method turned out to be most appropriate for a subset of the ages 335 tested). This flexibility was necessary because labs differ in their ability to recruit infants of 336

³³⁷ different ages.

Lab participation criterion. During study planning, we used data from MetaLab 338 (Bergmann et al., 2018) to compute the meta-analytic mean effect size for IDS preference; 339 the resulting value was Cohen's d = .72. In a paired t-test, 95% power to detect this effect 340 requires 27 participants, and 80% power requires 17. On the basis of these calculations, we 341 asked participating labs to commit to samples with a minimum of N = 32 in a single age 342 group. However, given that for many of our analyses, power across labs is more critical than 343 within a lab (Judd, Westfall, & Kenny, 2017), we allowed labs to contribute a "half sample" 344 of N = 16, with the assumption that this would increase the number of laboratories capable 345 of participating and allow more laboratories to contribute samples from multiple age bins. 346 We specified that labs should recruit with respect to the desired demographic characteristics 347 of the study (e.g., full-term infants; see below for full list of exclusion criteria). Given this 348 recruitment strategy, however, we asked that sample Ns be calculated on the basis of the 349 number of total infants tested, not the infants retained after exclusions (which were 350 performed centrally as part of the broader data analysis, not at the lab level). 351

We included data from a lab in our analysis if they were able to achieve the minimum N required for a half-sample in their age bin (N = 16) by the end date of testing and if, after exclusions, they contributed 10 or more data points. If a lab collected more than their required sample, we included the extra data as well. Laboratories were cautioned not to consider the data (e.g., whether a statistically significant effect was evident) in their lab internal decision-making regarding how many infants to recruit/when to stop recruitment.

358 Participants

Our final sample was comprised of 2329 monolingual infants from 67 labs (mean sample size per lab: 34.76, SD = 20.33, range: 10 – 93; 45 contributed data at multiple ages). Demographic exclusions were primarily implemented during recruitment; despite this,
additional infants were tested and excluded based on preset criteria (see Exclusions below for
percentages). In addition, 2 labs registered to participate but failed to collect data from at
least 10 included infants, and so their data were not included. Information about all
included labs is given in Table 1.

The mean age of infants included in the study was 291.99 days (range: 92 - 456). 366 There were 310 infants in the 3- to 6-month-old bin (23 labs), 772 infants in the 6- to 367 9-month-old bin (49 labs), 554 infants in the 9- to 12-month-old bin (35 labs), and 693 368 infants in the 12- to 15-month-old bin (42 labs). Many labs collected data in more than one 369 bin. Of the total sample, 1066 infants (from 30 labs) were acquiring NAE, and 1263 infants 370 (from 37 labs) were acquiring a language other than NAE. As discussed above, a separate 371 sample of bilingual children was tested in a parallel investigation, but these data are not 372 reported in the current manuscript. 373

Table 1

Statistics of the included labs. N refers to the number of infants included in the final analysis. English from the US and Canada are both treated as North American English.

374

375 Materials

Visual stimuli. For labs using central fixation or eye tracking methods, a brightly
colored static checkerboard was used as the fixation stimulus, and a small engaging video (an
animation of colorful rings decreasing in size) as an attention-getter. For labs using HPP, we

asked labs to use their typical visual stimulus, which varied considerably across laboratories.
Some labs used flashing lights as the visual fixation stimulus (the original protocol that was
developed in the 1980s), while others used a variety of other visual displays on video screens
(e.g., a looming circle).

The goal of our stimulus creation effort was to construct a set of Speech stimuli. 383 recordings of naturalistic IDS and ADS gathered from a variety of mothers speaking to their 384 infants. To do so, we gathered a set of recordings of mothers speaking to their infants and to 385 experimenters, selected a subset of individual utterances from these (see below), and then 386 constructed stimulus items from this subset. All other characteristics of the recordings 387 besides register (IDS vs. ADS) were as balanced as possible across clips. Based on our 388 intuitions and the data from the norming ratings described below, we consider these stimuli 380 to be representative of naturally produced IDS and ADS across middle- and high-SES 390 mothers in North America. Although future studies could attempt to vary particular aspects 391 of the IDS systematically (e.g., age of the mother, age of the infant being spoken to, dialect), 392 we did not do so here. Our stimulus elicitation method was designed to meet the competing 393 considerations of laboratory control and naturalism. 394

Source recordings were collected in two laboratories, one in central Canada and one in 395 the Northeastern United States. The recorded mothers had infants whose ages ranged from 396 122 - 250 days. The same recording procedures were followed in both laboratories. 397 Recordings were collected in an infant-friendly greeting area/testing room using a simple 398 lapel clip-on microphone connected to a smartphone (iPhone 5s or 6s), with the "Voice 399 Record" or "Voice Record Pro" apps (Dayana Networks Ltd.) in the Canadian lab, and the 400 "Voice Memos" app (Apple Inc.) in the US lab. The targets for conversation were objects in 401 an opaque bag: five familiar objects (a ball, a shoe, a cup, a block, a train) and five 402 unfamiliar objects (a sieve, a globe, a whisk, a flag, and a bag of yeast). To ensure that 403 mothers used consistent labels, a small sticker was affixed to each object showing its name. 404

Each object was taken out of the bag one at a time and the mother was asked to talk about the object, either to her baby (for the IDS samples) or to an experimenter (for the ADS samples) until she ran out of things to say; at this point the next object was taken out of the bag. Recording stopped when all the objects had been removed from the bag and had been talked about. Order of IDS and ADS recording was counterbalanced across participants. A total of 11 mothers were recorded in Canada and four in the United States.

There were a total of 179 unedited minutes of recording from Canada and 44 from the United States. A first-pass selection of low-noise IDS and ADS samples yielded 1281 utterances, for a total of 4479 s. From this first pass, 238 utterances were selected that were considered to be the best examples of IDS and ADS and met other basic stimulus selection criteria (e.g., did not contain laughter or the baby's name).

This library of 238 utterances was then normed on five variables: accent, affect, 416 naturalness, noisiness, and IDS-ness. The goal of this norming was to gather intuitive 417 judgments about each variable so as to identify utterances that were clearly anomalous in 418 some respect and exclude them. In each case, a set of naïve, North American 419 English-speaking adults recruited from Amazon Mechanical Turk (MTurk) listened to all 238 420 of the utterances and rated them on a 7-point Likert scale. Raters were assigned randomly 421 to one of the five variables, with the number of participants assigned to a particular rating 422 task ranging between eight and 18 due to variability in random assignment. Affect and IDS 423 ratings were made using low-pass filtered recordings (a 120-Hz filter with standard rolloff was 424 applied twice using the sox software package). These ratings were intended to give us a 425 principled basis on which to exclude clips that were outliers on particular dimensions (such 426 as having odd affect or background noise). In general, with the exception of IDS-ness, 427 ratings were not highly variable across clips (the largest SD was .85, for noise ratings). 428

Ratings from the tasks were then used to produce a set of utterances such that accent was rated similar to "standard English" (ratings < 3, with 1 being completely standard), ⁴³¹ naturalness was rated high (> 4, with 7 being completely natural), noisiness was rated low ⁴³² (< 4, with 1 being noiseless), and IDS and ADS clips were consistently distinguished (with ⁴³³ IDS having ratings > 4 and ADS having ratings < 4, with 7 being clearly directed at a baby ⁴³⁴ or child). This procedure resulted in 163 total utterances that met our inclusion criteria.

Our next goal was to create eight IDS and eight ADS stimuli that were exactly 18 s in length, each containing utterances from the set we created. To do so, we assembled utterances from our filtered set. All clips were root mean square amplitude-normalized to 70 dB sound pressure level (SPL) before assembly, and then the final stimuli were amplitude-renormalized to 70 dB SPL. We assembled the final stimuli considering the following issues:

Identity. Audio stimuli were constructed using clips from more than one mother. The
 number of different mothers included in a given stimulus was matched across IDS and
 ADS stimuli. In addition, multiple clips from the same mother were grouped together
 within a given stimulus in order to match the number of "mother transitions" across
 registers.

Lexical items. We matched the presence of object labels in the clips across IDS and
 ADS contexts. We also ensured an even distribution of the order in which each
 particular word was presented across stimuli and registers (ADS vs IDS).

Questions. IDS tends to include a much higher proportion of questions compared with
 ADS (Snow, 1977; Soderstrom, Blossom, Foygel, & Morgan, 2008). However, because
 the nature of the recording task may have served to inflate this difference, we
 preferentially selected declaratives over questions in the IDS sample. The final stimulus
 set contained 47% questions in the IDS samples and 3% questions in the ADS samples.
 We felt that retaining this naturally-occurring difference in IDS and ADS within our
 stimuli was more appropriate than precisely and artificially controlling for

456 utterance-type across registers.

Duration of individual clips. As expected, the utterances in IDS were much shorter
 than those in ADS, so it was not possible to match on duration or number of clips.
 Because there were more clips per stimulus in the IDS samples, there were also more
 utterances boundaries. This property is consistent with the literature on the natural
 characteristics of IDS (Martin, Igarashi, Jincho, & Mazuka, 2016).

Total duration. We fixed all stimuli to have a total duration of 18 s by concatenating
 individual utterance files into single audio files that were > 18 s in length, trimming
 these down to 18 s and fading the audio in and out with 0.5 s half-cosine windows.

Table 2 and Figure 1 provide additional details regarding the final stimulus set. Measurements were made using STRAIGHT (Kawahara & Morise, 2011), using default values for F0 extraction. For Figure 1, F0 values for voiced portions of the stimuli were collapsed into a series of logarithmically-spaced bins spanning the algorithm's F0 search range of 32-650 Hz.

Table 3 provides a comparison of our stimuli to a sample of others that have been used 470 previously in the IDS preference literature. Across studies, the only statistic that was 471 reported reliably across papers was the mean pitch (F0) for IDS and ADS and even this one 472 was only reported in about half the studies we sampled. Various measures of variability were 473 reported in some studies (e.g., range within each sample, range across samples, standard 474 deviation), but due to variation in the length and number of different samples used in each 475 study, and a lack of systematicity in reporting, it was difficult to compare directly. 476 Numerically, the average IDS/ADS pitch difference in our materials was less extreme than 477 that found in previous studies. 478

To confirm that our composite IDS and ADS stimuli were rated as natural and that the more limited pitch difference between registers still led to the stimuli being categorized

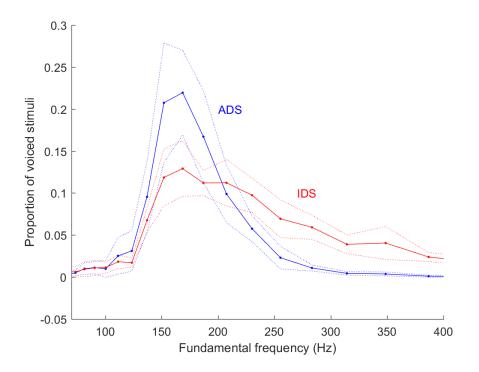

Figure 1. The distribution of F0 values for IDS and ADS is displayed as the proportion of voiced segments that fell in each F0 bin. Dashed lines show mean plus or minus one standard error across stimuli.

differently, we conducted another norming study. Using the same basic paradigm as above, 481 we collected a new sample of judgments from MTurk participants. Raters were randomly 482 assigned to listen to all 16 stimuli and judge either whether they were directed at 483 infants/children or adults (N = 22) or else whether the stimuli sounded natural (N = 27). 484 All IDS clips were judged extremely likely to be directed at infants or children (M = 6.74, 485 SD = .09, on a 1 – 7 rating scale), while all ADS clips were judged highly likely to be 486 directed to adults (M = 2.12, SD = .38). Both were judged to be relatively natural, with 487 the ADS, if anything, slightly more natural (M = 5.18, SD = .19) than the IDS (M = 4.47, SD = .19)488 SD = .31). In sum, because our stimuli were created from naturalistic productions from a 489 wide range of mothers, they were less extreme in their intonation, but they were judged as 490 natural and were easily identified as infant-directed. 491

Table 2

Characteristics of the IDS and ADS stimuli, with standard deviations computed across stimuli.

Measurement	IDS Mean	IDS SD	ADS Mean	ADS SD
Number of mothers speaking per stimulus	4.00	0.00	3.75	0.46

Table 3

492 **Procedure**

Basic Procedure. Each lab used the testing paradigm(s) with which they were
most familiar, among variants of three widely-used measurement methods: 20 laboratories
used the HPP, 16 used the single-screen central visual-fixation preference procedure (CF),
and 27 used single-screen central visual fixation with fixations recorded by a
corneal-reflection eye tracker (ET); four labs contributed data using two different methods.
All procedural instructions to participant labs can be found at https://osf.io/s3jca/.

To minimize researcher degrees of freedom, we asked participating labs to adhere to our instructions closely. Deviations from the basic protocol for each paradigm were necessary in some cases due to variation in the software and procedures used in each laboratory and were documented for future analysis.

1st vs. 2nd test session. In some laboratories, infants were sometimes tested in an
unrelated experiment during their visit, either prior to or following the IDS preference
experiment. Each lab noted whether infants completed the IDS preference experiment as
their 1st (and possibly only) or 2nd test session.

Onset of each trial. At the beginning of each trial, a centrally positioned visual stimulus (typically the study's standard attention getter, or a light in some HPP labs) was used to attract the infant's attention. Upon fixation, this event was followed by a visual stimulus (a checkerboard for CF and ET, a light or a similar video for HPP). The stimulus appeared to the left or right of the infant in HPP setups and in the center in CF and ET setups.

Trials. At the beginning of the session, there were two warm-up trials that familiarized infants with the general procedure. The auditory stimulus for warm-up trials was an 18-second clip of piano music, and the visual stimulus was identical to the test trials. These trials familiarized infants to the general experimental setup and highlighted the contingency between looking at the visual display and the onset of the auditory stimulus. We did not analyze data from these trials. Training trials were then followed by up to 16 test trials presenting the IDS and ADS auditory stimuli.

Minimum looking time. There was no minimum required looking time during data collection (i.e., trials were never repeated). A minimum looking time of 2 s was used during analysis for inclusion of a trial. The 2-s minimum trial time was chosen after discussion across laboratories regarding typical standards of practice on minimum trial length, which varied considerably across laboratories. This criterion was selected to ensure that the infant had sufficient time to hear enough of the stimulus to discriminate IDS from ADS.

Maximum looking time. On each test trial, infants could hear speech for a maximum of 18 s, corresponding to the duration of each sound file. For labs whose software could implement infant-controlled trial lengths, the trial ended if the infant looked away from the visual stimulus for two consecutive seconds. Otherwise, the trial continued until the stimulus ended.

Randomization. Four pseudo-random trial orders were created. Each order
contained four blocks, with each block containing two IDS and two ADS trials in alternating
order. Two blocks in each order began with IDS and the other two began with ADS. To
facilitate analyses of preference scores by item, the same IDS and ADS stimuli were always
paired with one another.

Volume. Each lab was asked to use a stimulus volume level that was consistent with their general lab practices – this decision was not standardized across labs. Labs were instead instructed to measure and report their average dB SPL level with and without a white noise reference audio clip playing, though not all contributing labs reported these measurements (N = 47). From these values, we calculated a signal to noise ratio for each lab, M = 1.95, SD = 0.43, range: 1.25 - 3.30.

Minimizing caregiver bias. We created a custom blend of instrumental music and a pastiche of stimulus materials triggered at random times and with random amplitude (available as part of the study materials). This masking stimulus was played to the caregiver over noise-attenuating headphones, to mask the IDS/ADS stimuli that the infant was hearing via external loudspeakers. Experimenters were instructed to play the masking music at a high (but comfortable and safe) volume.

Coding. Coding of looking times was conducted via the standard procedure in each lab. There were three methods of coding infant eye gaze: online coding by an experimenter via button press during the experimental session, offline coding of a video after the experimental session, or automatic coding collected by an eye tracker. In the case that we received online and offline coding data, we used the offline coding.

Minimizing experimenter bias. Experimenters making online coding decisions (in CF and HPP methods) were blind to the particular stimulus presented during testing trials, as they were either located in a different room from the infant, or were in the same room but were wearing noise-attenuating headphones and hearing the same masking stimuli as the infant's caregiver. Offline coding was conducted without direct access to the auditory stimuli.

Demographics. All labs were instructed to collect a set of basic participant 558 demographic information: sex, date of birth, estimated proportion language exposure for the 559 language(s) that they hear in their daily life, race/ethnicity (using categories appropriate for 560 the cultural and geographic context), preterm/fullterm status, history of ear infections, 561 known hearing or visual impairments, and known developmental concerns (e.g., 562 developmental disorders). Parents were also asked to report information about themselves 563 (gender, level of education, and native language/languages) and the child's siblings 564 (sex/gender and date of birth). A standard recommended participant questionnaire was 565

distributed to participating labs as part of the instructions, although labs were permitted to use their own forms as long as they gathered the necessary information. In addition, a subset of participating laboratories provided extensive additional information about infants and testing circumstances (not analyzed here), for use in planned followup projects.

570 General Lab Practices

Training of research assistants. Each lab was responsible for maintaining good experimenter training practices, and was expected to use the same rigor with the ManyBabies study as with any other study in their laboratory. Laboratories reported on which research assistant ran each infant using pseudonyms or numerical codes. Each laboratory completed a questionnaire regarding their training practices, the experience and academic status of each experimenter, and their basic participant greeting practices.

Reporting of technology mishaps and infant/parent behavior. Laboratories were asked to note relevant concerns, anomalies and comments according to their standard lab practices and these were provided along with the looking time data and converted to a standardized form during the central analysis. Examples of relevant concerns included the infant crying during testing, parents intervening in a way that would affect their infant's looking behavior (e.g., talking or pointing), or technical problems that prevented the normal presentation of experimental stimuli.

584 Videos

All laboratories provided a "walk-through" video that detailed their basic processes including greeting, consent and data collection and showing the physical characteristics of their laboratory. (In our preregistration we stated that further procedural documentation would be available, but standardized reporting for procedural decision-making proved difficult to develop and deploy.) In addition, we strongly encouraged laboratories to collect and share video recordings of their data collection according to what was permissible given their ethics approval and participant consent. If labs could not provide participant videos, they were asked to provide a video showing a run-through of their procedure and/or pictures and information regarding the study setup. A number of laboratories contributed these video recordings to Databrary, where they can be found by searching for "ManyBabies 1."

595 Exclusion Criteria

All data collected for the study (i.e., every infant for whom a data file was generated, regardless of how many trials were completed) were given to the analysis team for confirmatory analyses. Participants were only included in analysis if they met all of the criteria below. All exclusion rules are applied sequentially, and percentages reflect this sequential application to an initial sample prior to exclusions of 2754. N.B.: the first three criteria preemptively prevent participation (except in case of erroneously running the experiment with children outside of the inclusion guidelines).

Monolingual. Monolingual infants of any language background were included in the
 sample. Monolingual was defined as 90% parent-reported exposure to the native
 language. This cutoff score struck a balance between including most infants who are
 typically considered monolingual in infant language studies, while excluding those who
 might be considered bilingual (Byers-Heinlein, 2015). 162 (5.88%) infants were tested
 but did not meet this criterion.

• *Full-term*. We defined full term as gestation times greater than or equal to 37 weeks. Of the remaining sample, 62 (2.39%) infants were tested but did not meet this criterion.

• No diagnosed developmental disorders. We excluded infants with parent-reported developmental disorders (e.g., chromosomal abnormalities) or diagnosed hearing impairments. Of the remaining sample, 2 (0.08%) infants were tested but did not meet
this criterion. Due to concerns about the accuracy of parent reports, we did not
exclude infants based on parent-reported ear infections unless parents reported
medically-confirmed hearing loss.

Contributed usable data. A child must have contributed non-zero looking time on a 617 pair of test trials (i.e., one trial each of IDS and ADS from a particular stimulus pair), 618 after trial-level exclusions were applied, to be included in the study. Of the remaining 619 sample, 41 (1.65%) infants were tested but did not meet these criteria. We adopted 620 this relatively liberal inclusion criterion even though it is at variance with the more 621 stringent standards that are typically used in infancy research. We were interested in 622 maximizing the amount of data from each lab we were able to include in the initial 623 analysis, and our paradigm was, by design, less customized for any particular age 624 group (and hence likely to produce greater data loss, especially for older children, who 625 tend to habituate more quickly). In the exploratory analyses below, we consider how 626 exclusion decisions affected our effect size estimates. 627

After these exclusions were applied, participants could also be excluded for analysis 628 based on session-level errors, including: equipment error (e.g., no sound or visuals on the 629 first pair of trials), experimenter error (e.g., an experimenter was unblinded in setups where 630 infant looking was measured by live button press), or evidence of consistent parent/outside 631 interference noted by participating labs (e.g., talking or pointing by parents, construction 632 noise, sibling pounding on door). 78 (3.18%) infants for whom we had other reported data 633 were dropped from analysis due to session-level error. This number is likely an underestimate, 634 however. Many participating labs did not provide data for all children with session-level 635 errors; in addition, session-level errors were not classified consistently across labs, so an 636 accurate classification of the proportion of different types of errors was not possible. 637

638

We further excluded individual trials that were reported as having issues (e.g.,

⁶³⁹ fussiness, incorrect stimulus, single instance of parent or sibling interference). A total of 4471
⁶⁴⁰ (10.61%) trials were affected by such errors. As with session level errors, classification of
⁶⁴¹ these was inconsistent across participating labs, but the most common source of trial-level
⁶⁴² errors was infant fussiness.

Based on our trial-length minimum, we also excluded 6027 (16.13%) trials with total looking times shorter than 2 s. These trials are analyzed as "missing" in our planned analysis below.

As discussed above, we included a lab's data if they were able to achieve the minimum N required for a half-sample and if, after exclusions, they contributed 10 or more data points. 11 (0.47%) infants from 2 labs were not included in the final sample because of this criterion.

649 Post-Data Collection Methods Addendum

As the first experimental cross-laboratory infant study of this scale, there were a 650 number of unanticipated issues that arose during data collection within individual labs and at 651 the study level, which resulted in deviations from our registered protocol. All such cases were 652 documented and decisions were made without consideration of their impact on the results. 653 Fuller documentation can be found accompanying our shared data; here we summarize the 654 nature and extent of these deviations. Note that some of these deviations were the result of 655 typical within-laboratory protocol deviation (experimenter error, etc.) while others stemmed 656 from the additional challenges inherent in harmonizing methodology and data format across 657 such a large number of laboratories with different lab-internal protocols and standards. 658

⁶⁵⁹ These protocol deviations include the following:

• Before labs had commenced data collection, we altered our attention-getter stimulus to be a precessing annulus accompanied by chimes (to address the concern that a laughing baby might be more associated with infant-directed speech); some labs usedthe old stimulus.

• Variation in trial length beyond the assumed maximum of 18 s emerged due to deviations in lab's protocols for a variety of reasons. In all cases, looking times on these trials were truncated to 18 s.

• A number of labs provided data from infants that were within the 3–15 month age range, but outside of the submitting lab's pre-registered age bin. These infants were included in the analyses.

Many labs deviated from their pre-registered sample size due to constraints on testing
 resources. We included these labs provided they met the minimum inclusion criteria for
 the study as a whole. All such labs certified that they did not make decisions regarding
 sample size on a data-dependent basis.

• A number of laboratories marked participants as session-level errors for reasons other than equipment error, experimenter error or outside interference.

This last point bears further discussion. Some labs marked participants as exclusions 676 at the participant level for trial-level errors (e.g. infant fussy, parental interference), even 677 though there was sufficient trial-level data available for analysis. Similarly, individual trials 678 were sometimes marked as errors for reasons related to participant-level issues. All trial-level 679 and participant-level errors were reviewed centrally by at least two coders using all available 680 information in the spreadsheet to determine whether a trial-level or participant-level error 681 was appropriate. Specific information about each trial or participant error coding that was 682 changed during this process can be found by reviewing metadata within the data analysis 683 codebase. 684

In total, 313 participants from 50 labs previously marked as participant-level exclusions were retained for further processing and analysis. Participants originally coded as having session-level errors were recoded for the following reasons: when the participant-level

exclusion was based solely on the existence of trial-level errors (190 infants), when exclusion 688 was based on a different exclusion criterion (e.g., participants were out of the age range or 689 were preterm) (93 infants), or if an issue identified by the lab at the participant level was 690 deemed acceptable by the central analysis team (e.g., if a lab implemented a slightly different 691 look-away criterion, see below) (30 infants). Note that many of the retained participants 692 were subsequently excluded at other points in the analysis pipeline because, although they 693 did not meet the criteria for session-level errors, they did meet the conditions for other 694 exclusion criteria (e.g., participants did not contribute enough useable trials or were excluded 695 based on language exposure). 696

In addition to recoding session-level errors, we also corrected the coding of trial-level 697 errors where appropriate. 778 total trial-level errors from 62 participants in 16 different labs 698 were recoded. The majority of trials were corrected when labs coded a participant-level error 699 (e.g. age exclusion) on the trial level (584 trials) or coded a trial-level error on the 700 participant level (e.g., if labs marked a participant as a session-level error for fussiness on a 701 specific trial, but did not code the affected trials as errors) (133 trials). Other trials were 702 corrected when subsequent investigation of lab notes and discussion with lab members 703 revealed that the original trial-level error code needed to be changed (61 trials). 704

In addition, a variety of errors were found (e.g., pilot participants not properly excluded but noted in the comments) and fixed within the spreadsheets. Video data were not reviewed centrally, although in some cases where a question arose, the laboratory reviewed their own video in-house in order to respond. The entire process has been carefully documented and can be accessed upon request, but because in some cases this included identifiable information about participants, it is not possible to share it publicly.

711 Other reported protocol deviations included: No preregistration form submitted (1 712 lab); trial look-away time set to 3 s for some participants (1 lab); lab temporarily moved 713 location during data collection (1 lab); minor protocol technical changes after start of data ⁷¹⁴ collection (2 labs); alternated left-right presentation and tested skin conduction during
⁷¹⁵ procedure (1 lab); procedural differences related to high-chair usage (1 lab); attention-getter
⁷¹⁶ deviation (4 labs); use of a pinwheel rather than checkerboard as the main visual fixation
⁷¹⁷ stimulus in HPP (1 lab).

We also detected a large number of data submission errors (typographical or otherwise) 718 as a result of the comprehensive checking process in analysis. These were resolved when 719 necessary by contacting the original lab. In general, we were inclusive of data with minor 720 protocol deviations, and erred on the side of excluding data, when necessary, at the trial 721 rather than participant level. A few demographic variables required greater central scrutiny 722 than originally anticipated. Most notably, there was considerable variability in the 723 interpretation of preterm and bilingual designations (despite centrally-dictated standards). 724 When necessary, we recoded lab data so as to conform to the original protocol definitions. 725

There was an ambiguity in our lab-level exclusion criteria between whether labs would be included if they contributed 10 or more datapoints, or more than 10 datapoints. We chose the more liberal of these two criteria.

Finally, two labs submitted data after the deadline. In one case this was due to a communication error; in the other case, the lab continued data collection, resulting in 8 additional infants being tested. Both datasets are included in the final analysis here.

732

Results

733 Confirmatory Analyses

Data processing and analytic framework. All planned analyses were
pre-registered in our initial registered report submission (available at https://osf.io/vd789/).
Our primary dependent variable of interest was looking time (LT). Looking time was defined

as time spent fixating the screen (for central fixation and eye tracking methods, and some
HPP set-ups) or light (HPP) during test trials; LT scores did not count any time spent
looking away from the screen, even if looks away were below the threshold for terminating a
trial. Since looking times are non-normally distributed, following Csibra, Hernik, Mascaro,
Tatone, and Lengyel (2016), we log-transformed all looking times prior to statistical analysis
(we refer to this transformed variable as "log LT").

We adopted two complementary analytic frameworks: meta-analysis and mixed-effects 743 regression. In the meta-analytic framework, we conducted standard analyses within each lab 744 and then estimated variability in the result of this analysis across labs. The meta-analytic 745 approach has a number of advantages over the mixed-effects approach, including the use of 746 simple within-lab analyses, the ability to estimate cross-lab variability directly, and the 747 possibility of making direct comparisons with the standardized effect sizes that have been 748 estimated in previous meta-analyses. However, the standard random-effects meta-analytic 749 model is designed for a case where the raw data are unavailable and procedures and 750 data-types are not standardized. In contrast, in our situation, procedures and data were 751 standardized across labs and relevant moderators were recorded. The availability of 752 trial-by-trial data across all labs allows us to use mixed-effects models, which account for the 753 nesting and crossing of random effects (e.g., subjects nested within labs, items crossed across 754 labs), and can provide more accurate estimates of the main effect and moderators. Both 755 analyses were therefore included to allow for the most comprehensive understanding of the 756 variance in the data. 757

Our meta-analyses were conducted as follows. The datasets provided by each lab were considered as separate "studies." For each lab's dataset, we first computed individual infants' IDS preference by 1) subtracting looking times to each IDS trial from its paired ADS trial (excluding trial pairs with missing data) and 2) computing a mean difference score (across trial pairs). Then we computed a group IDS preference for each lab and infant age group using dz, a version of Cohen's standard d statistic, computed as the average of infants' IDS preference scores divided by the standard deviation of those scores. We then used standard random effects meta-analysis fit using REML with the metafor package (Viechtbauer, 2010).

In our initial analysis plan, we did not anticipate that a large number of labs would 766 collect data outside of their planned samples. For example, many labs contributed a sample 767 of children within a specific age bin as well as several children that fell outside of that age 768 bin, or a sample of children using one method and a handful of children with another. While 769 we include these children in the mixed-effects analyses described below, we worried that the 770 inclusion of many unplanned samples of just one or two infants in the meta-analytic models 771 would excessively increase lab-level variance. Thus, for only the meta-analyses, we include 772 only samples (e.g., age, language, or method groups) with ten or more infants. 773

Our mixed effects models, fit to the entire dataset collected from the 67 labs, were specified as:

$$DV \sim IV_1 + IV_2 + ... + (...|subject) + (...|item) + (...|lab)$$

The goal of this framework was to examine effects of the independent variables 776 (notated IV) on the dependent variable (DV), while controlling for variation in both the DV 777 ("random intercepts") and the relationship of the IV to the DV ("random slopes") based on 778 relevant grouping units (subjects, items, and labs). The use of mixed-effects models also 779 allowed us to move away from using difference scores as the dependent variable of interest. 780 While difference scores simplify the process of calculating effect sizes for the meta-regression, 781 their use requires that trials be paired, so some collected data (i.e., unpaired trials) cannot 782 be analyzed. In the mixed effects framework, in contrast, looking time on individual trials is 783 the dependent measure, ensuring that all trials can be included. 784

In our mixed-effects models, we planned a maximal random effects structure (Barr, 785 Levy, Scheepers, & Tily, 2013), which entails specifying all random effects that are 786 appropriate for the experimental design (e.g., IDS/ADS trial type can be nested within 787 subjects - since each infant heard stimuli in both conditions — but cannot be nested within 788 items since each item is unique to its trial type). In cases of mixed-effects models that failed 789 to converge, we pursued an iterative pruning strategy. We began by removing random slopes 790 nested within items (as that grouping was of least theoretical interest) and next removing 791 random slopes nested within subjects and then labs. We then removed random intercepts 792 from groupings in the same order, retaining effects of trial type until last since these were of 793 greatest theoretical interest. We fit all models using the lme4 package (Bates, Mächler, 794 Bolker, & Walker, 2015) and computed p values using the lmerTest package (Kuznetsova, 795 Brockhoff, & Christensen, 2017). 796

IDS preference. What was the overall magnitude of the IDS preference we observed? This question is answered within the cross-lab meta-analysis by fitting the main effect model specified by $dz \sim 1$ to the 108 separate group means and variances (after aggregating by lab and age group). The mean effect size estimate was 0.35 (CI = [0.29 -0.42], z = 10.67, p < .001). A forest plot for this meta-analysis is shown in Figure 2. Further, 1373/2329 infants (58.95%) showed a numerical preference for IDS.

Independent relationship of IDS preference to moderating variables. We 803 next fit a set of moderated meta-analytic models. We began by examining the relationship of 804 IDS preferences to age, using the average age in months for each lab's contributed sample as 805 the moderator value. Labs that contributed samples from two age bins had values added 806 separately for each age (because of the small number of these, we did not model this 807 dependency between labs). For ease of interpretation, we centered age in this analysis. The 808 age-moderated model, $dz \sim 1 + \text{age}$, yielded an estimated main effect of 0.35 (CI = [0.29 -809 0.41], z = 11.47, p < .001) and an age effect of 0.05 (CI = [0.03 - 0.07], z = 4.89, p < .001). 810

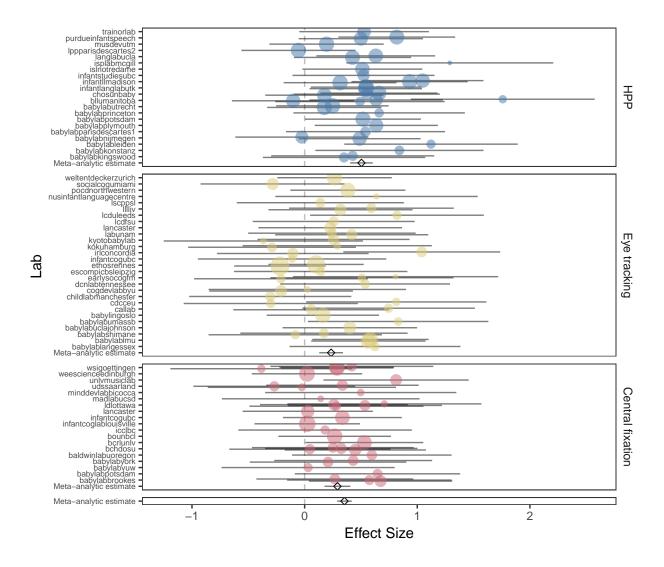

Figure 2. Forest plot. Standardized effect sizes are shown for each lab, with error bars showing 95% confidence intervals. Labs are grouped by method. Points are scaled by inverse variance and colored by experimental method. In each panel, the diamond and associated interval represents the meta-analytic estimate from the method-moderated model and its 95% confidence interval. The bottom panel shows the global meta-analytic estimate from the unmoderated model.

This positive age coefficient indicated that the measured IDS preference was on average larger for older children. Age trends are plotted in Figure 3.

We next investigated effects of experimental method, with method dummy-coded using

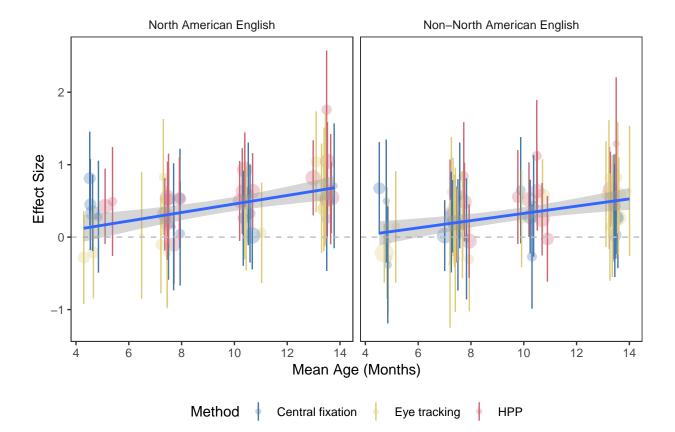

Figure 3. Lab effect size estimates plotted by age and method. Subplots show language groups. Standardized effect sizes are shown for each lab, with error bars showing 95% confidence intervals. Points are scaled by number of participants and colored by experimental method; they are slightly transparent to avoid overplotting.

single-screen central fixation as the reference level. The method-moderated model

 $(dz \sim 1 + \text{method})$ yielded a reference-level intercept of 0.29 (CI = [0.18 - 0.41], z = 4.98, p < .001), reflecting the mean effect size for single-screen presentation. The HPP yielded an additional effect of 0.21 (CI = [0.06 - 0.37], z = 2.74, p = .006), indicating a substantial gain in measured IDS preference for those labs using HPP as compared with single-screen central fixation. In contrast, eye-tracking yielded an effect of -0.06 (CI = [-0.21 - 0.10], z = -0.71, p = .479), indicating a slight, non-significant decrease in measured effect size for eye-tracking relative to single-screen central fixation.

The language-moderated model ($dz \sim 1 + \text{language}$) was fit with language group coded

822

as a categorical variable indicating whether infants were tested in a lab in which NAE was the standard language (e.g., in the United States or Canada). The reference level effect (i.e., not NAE) was 0.29 (CI = [0.20 - 0.37], z = 6.56, p < .001), while for infants in North American labs, the effect was increased by 0.15 (CI = [0.02 - 0.27], z = 2.26, p = .024). Thus, measured IDS preferences were higher in those infants for whom the stimuli were native-language congruent.

Joint relationship of IDS preference to moderating variables. Because infant age, language, and method were confounded across labs (labs with particular methods also chose specific sample age ranges, and these choices were not independent), we next turn to the mixed- effects modeling framework to estimate subject-level age effects and lab-level method effects. To help visualize the spread of subject-level effects, Figure 4 shows IDS preferences for individual participants.

835 Our main model was:

log lt ~trial type * method + trial type * trial num + age * trial num +
trial type * age * language+
 (trial type * trial num | subid)+
 (trial type * age | lab)+
 (method + age * language | item)

Trial type, language, and method were dummy-coded (with ADS trials, non-NAE, and single-screen method) as the reference level; thus, coefficients are interpretable such that e.g., positive effects of trial type indicate longer looking to IDS. To increase the interpretability of coefficients, age (in months) was centered and trial number was coded with trial 1 as the reference level.

We specified this model to minimize higher-order interactions but preserve 841 theoretically-important interactions. We included main effects of trial type, method, 842 language, age, and trial number, capturing the basic effects of each on looking time (e.g., 843 longer looking times for IDS, shorter looking times on later trials). In addition, we included 844 two-way interactions of trial type with method (modeling the possibility that some methods 845 show larger IDS preferences) and trial type with trial number (modeling the possibility of 846 faster habituation to ADS) as well as age and trial number (modeling faster habituation for 847 older children). We also included two- and three-way interactions of age, trial type, and 848 language (modeling possible developmental changes in IDS preference across age and 840 language group). Both developmental effects and trial effects are treated linearly in this 850 model; although both likely have non-linear effects, adding quadratic or other effects would 851 have substantially increased model complexity. After pruning random effects for 852 non-convergence,¹ our final model specification was: 853

> log lt \sim trial type * method + trial type * trial num + age * trial num + trial type * age * language + (1 | subid)+ (1 | lab)+ (1 | lab)+ (1 | item). (2)

⁸⁵⁴ Table 4 shows coefficient estimates from this model.

Overall, the fitted coefficients of the mixed effects model were consistent with the results of the individual meta-analyses. Within the structure of the mixed effects model, IDS preferences are shown by positive coefficients on the IDS predictor (reflecting greater looking times to IDS stimuli). The fitted model shows a significant positive effect of IDS stimuli,

 $^{^1}$ Pruning was done using models fitted with 'lme4' version 1.1-21.

IDS * Age * NAE	0.004	0.004	1.050	0.292	

consistent with a global IDS preference. Consistent with the age- and language-moderated meta-analyses, there were significant and positive two-way interations of IDS with age and with NAE, suggesting greater IDS preferences for older children and for children in NAE contexts. Further, there was a positive interaction with the HPP method, consistent with the method-moderated model. There was not a significant three-way interaction of IDS, age, and NAE, however, suggesting that there was not a reliable differential change in IDS preference for older children in NAE contexts over and above that expected based on each of these factors alone.

In addition to these results, a number of other factors were significant predictors of looking time. Looking time decreased across trials, and did so especially for older children, generally confirming that all infants habituated to our experimental stimuli and older infants did so more quickly. Further, eye-tracking led to lower looking times overall across stimulus classes.

North American English — FALSE - - TRUE Method — Central fixation — Eye tracking — HPP

Figure 4. Simple linear trends for IDS preference by age and language group, plotted (A) with individual participants' preferences and (B) without individual participants' preferences to show trends more effectively.

Effects of second-session testing on IDS preference. We preregistered an analysis of whether second-session infants showed a different pattern of infant-directed speech preference. Only 6 labs contributed second-session infants, however, with a total of only 0 infants represented. Thus, we did not fit the full, pre-registered mixed-effects model
for this variable as we did not have enough variability on the important covariates to
estimate this variable. As an exploratory analysis, we note that 19/41 second-session infants
(46.30% [31.60 - 61.30]) showed a numerical preference for IDS. This number was numerically
different but not distinguishable statistically from the 58.95% of IDS preferences in the
first-session infants, likely due to the small sample of second-session infants.

Sex and IDS preference. In order to investigate effects of biological sex on IDS preference, we fit the model specified above with the addition of a sex main effect and trial type by sex interaction.² Female was coded as the reference level, so effects are stated in terms of changes for male infants. The main effect of sex $\beta = 0.01$ (SE = 0.02, p = 0.67) and the interaction with trial type was $\beta = -0.01$ (SE = 0.01, p = 0.56). These predictors were small and nonsignificant, suggesting that sex was not a strong determinant of measured IDS preferences in our data.

Moderator effects on missing data. One further question regarding our data was 888 whether particular moderator variables affected not just the amount of looking time we 889 recorded, but whether children looked at all during a trial. To test for effects of moderators 890 on the presence of missing data, we constructed a categorical variable (missing), which was 891 true if a trial had no included looking time (e.g., no looking recorded, a look under 2 s, or no 892 looking because the infant had already terminated the experiment) and false otherwise. We 893 fit a logistic version mixed-effects model with all two-way interactions between method, age, 894 and trial number, using the specification: 895

 $^{^2}$ Because this model did not converge, following our protocol, we pruned random effects of item.

missing \sim method * age + method * trial num + age * trial num +

$$(1 | subid)+$$

$$(trial num * age | lab)+$$

$$(method + age | item).$$

$$(3)$$

⁸⁹⁶ After pruning for non-convergence, our final model specification was:

missing
$$\sim$$
method * age + method * trial num + age * trial num + (4) (1 | lab).

Table 5 shows coefficient estimates from this model. To aid convergence, we centered and 897 scaled age and trial number, and set single screen presentation as the reference level. Positive 898 coefficients indicate a higher probability of missing data. Older children and later trials had 899 greater amounts of missing data, consistent with the idea that all children habituated to the 900 stimuli, but that older children habituated faster. There was also a significant negative 901 interaction of age and eye-tracking, suggesting that data loss for eye-tracking was 902 substantially greater in younger children and lower in older children (we return to this issue 903 in the general discussion). Other coefficients were relatively small and nonsignificant. 904

905 Exploratory Analyses

Meta-analytic heterogeneity. One question of interest was whether we observed any meta-analytic heterogeneity in the data. When a meta-analysis shows heterogeneity, that finding indicates the presence of unexplained variance in effect size over and above that due to sampling variation; the τ^2 provides an estimate of the total heterogeneity in our models. We further assess heterogeneity using the I^2 statistic (Higgins, Thompson, Deeks, &

Table 5

Altman, 2003), which quantifies the proportion of total variation in estimates that is due to heterogeneity. We also report the results of a standard hypothesis test for heterogeneity, the Cochran Q test; when this test is statistically significant, that indicates that the null hypothesis of homogeneity of variance can be rejected (Huedo-Medina, Sanchez-Meca, Marin-Martinez, & Botella, 2006).

In our primary, intercept-only meta-analytic model, $\tau^2 = 0.01\%$, $I^2 = 12.39\%$, and Q(107) = 122, p = 0.15. In the language-moderated model, $\tau^2 = 0.01\%$, $I^2 = 7.76\%$, and Q(106) = 116.18, p = 0.23. In the age-moderated model, $\tau^2 = 0\%$, $I^2 = 0\%$, and Q(106) = 98.06, p = 0.70. Finally, in the method-moderated model, $\tau^2 = 0\%$, $I^2 = 3.20\%$, and Q(105) = 106.78, p = 0.43. In none of these could we reject the null hypothesis of no heterogeneity beyond sampling variation, and in no case was the magnitude of observed heterogeneity large. Although there were reliable moderators (see meta-analytic results
above), these moderators were quite small in magnitude relative to the sampling variation in
individual lab effect size estimates (because of the small median sample size within each lab).

Exclusion criteria. Because our criterion for including infants in the analysis was 925 so liberal (infants needed to contribute data from only two trials to be included), we next 926 conducted an exploration of the effects of different inclusion rules on the results we reported 927 above. In particular, we calculated the meta-analytic effect size with 4 trials and 8 trials as 928 minimum inclusion criteria. For a minimum of 4 trials, the effect size was 0.42 (CI = [0.35 -929 0.48, z = 12.05, p < .001) and for a minimum of 8 trials the effect size was 0.48 (CI = [0.40 -930 0.57], z = 11.23, p < .001). In comparison, our original results showed a meta-analytic effect 931 size of 0.35 (CI = [0.29 - 0.42], z = 10.67, p < .001). Furthermore, we computed effect sizes 932 for each method for each of these additional exclusion criteria (see Table 6). Overall, more 933 stringent inclusion criteria yielded substantially larger effects, although they also led to 934 substantial data loss (especially for eve-tracking labs). 935

Table 6

Meta-analytic effect size (dz), standard error (SE) and percentage of included participants for three different exclusion criteria

	2 Trials		4 Trials			8 Trials

936

General Discussion

We designed a large-scale, multi-lab study of infants' preference for IDS and invited infancy researchers to participate. Our call for participation resulted in contributions from 69 labs, representing a total of 2845 infants from 16 countries, 2329 of which were included in the final sample used for analysis (see Table 1). We believe that the resulting dataset represents the largest laboratory study of infancy to date. We begin our discussion by summarizing the principal results of the study with respect to four critical analytic questions and then discuss limitations of the study as well as future directions.

944 Summary of Findings

Our first goal was to address the issue of replicability by providing a pre-registered, unbiased measure of the magnitude of infants' preference for IDS over ADS. We expected to replicate prior demonstrations of the existence of an IDS preference in infant listeners, and our study indeed confirms the expected effect. Our overall meta-analytic mean is smaller in size than the effect found in a preceding meta-analysis of the literature, however (Bergmann et al., 2018; Dunst et al., 2012).

While one possible interpretation of this finding is that previous effect sizes were 951 inflated by publication bias, there are other possible explanations as well. In an individual 952 laboratory, the methodology would be tailored to the specific research question, age range 953 and other characteristics of the infants tested (or conversely, research questions would be 954 tailored to the existing methodological expertise of the laboratory). The approach used here, 955 namely applying multiple methodologies to the same research question across diverse age 956 ranges and samples of infants including non-native English learning infants, may have led to 957 an underestimate of the true effect size (i.e., because an ideal choice of presentation details 958 that would maximize effect sizes might differ between methods and across ages, versus the 959

⁹⁶⁰ compromise protocol used here). Further, our protocol included several decisions that might
⁹⁶¹ have decreased effect size, including both our stimuli's relatively less extreme acoustic
⁹⁶² characteristics, the use of multiple speakers, and our less stringent participant inclusion
⁹⁶³ criteria (both discussed below).

Our second goal was to examine possible age effects in the preference for IDS. 964 Consistent with the prior published meta-analysis (Dunst et al., 2012) and with idea that 965 preference for IDS grows in response to experience with positive social interactions – but in 966 contrast with some other reports in the literature (e.g., Hayashi et al., 2001; Newman & 967 Hussain, 2006; Segal & Newman, 2015) – we found an increase in IDS preference across 968 development. Further, the magnitude of the positive developmental change is considerable, 960 at 0.05 standard deviations per month. This finding suggests that the preference for IDS is 970 at a minimum modulated by experience and/or maturation. 971

As with any other developmental trend, however, age-related change may be driven by 972 changes in factors other than the underlying construct. First, as we will discuss in detail 973 below, characteristics of the stimuli may be best suited for an older age range. Second, 974 stronger effects may result from a more robust or more measurable behavioral response on 975 the part of older infants, independent of an underlying preference. Some evidence in favour 976 of this possibility stems from examining the data in MetaLab, an online databank for 977 meta-analysis in infant research: most meta-analyses show an increase in absolute effect size 978 as infants mature, independent of the research question (see e.g., Bergmann et al., 2018). 979

Our third goal was to examine how the preference for IDS varies based on the differing linguistic experiences of infants growing up across different linguistic communities. We found a preference for North American English IDS over North American English ADS even for participants for whom this was not their native language or dialect. This finding replicates previous work (Werker et al., 1994). However, in our study, North American English-exposed infants showed the strongest preference. Note that our findings do not support the idea of a simple attentional effect (infants attending more to speech overall when presented in their
native language): The effect of language background on overall (as opposed to preferential)
looking times is not large in our regression models.

There are several possible interpretations of the native language effect we observed. 989 One possibility is that as infants become experts in their native language phonology and 990 begin to acquire word meanings, they listen to speech in their own language differently, 991 starting to process what's being said not just as "speech" or "register" per se but as 992 meaningful language (Gervain & Mehler, 2010; Johnson, 2016). For infants hearing a foreign 993 language or even dialect, the ability to listen in this "deeper" or more predictive way is not 994 available. Another possibility is processing speech in an unfamiliar language requires more 995 attentional resources, leaving fewer attentional resources to process some of the 996 characteristics that may differentiate IDS and ADS. In either situation, preference for IDS 997 may depend in part on the similarity to one's native language experiences with IDS. This 998 idea is somewhat supported by the age effect we observed; however, we did not observe a 999 three-way interaction between age, stimulus type, and language background, which would 1000 have been a prediction of this interpretation. Companion data in several non-North 1003 American English language communities using native language stimuli created using the 1002 ManyBabies 1 protocol are currently under development and may shed further light on this 1003 issue. 1004

Our fourth and final goal was to examine differences across methodological approaches in the measured experimental effect. We found a stronger effect when using HPP than central fixation or eye-tracking approaches. One potential interpretation of this finding is that the greater effort on the part of the infant in HPP (i.e., a turning of the head, as opposed to small eye movements) leads to stronger engagement in the task and therefore to stronger effects.

¹⁰¹¹ It is important to keep in mind, however, that methodology was not randomly assigned

to laboratories, and the characteristics of laboratories probably varied systematically with 1012 their methodological choices. It may well be, for example, that laboratories with more 1013 expertise in infant language acquisition research were more likely to use HPP. Furthermore, 1014 these findings should not be interpreted as suggesting that HPP would be best suited for all 1015 research questions. Instead, a more modest interpretation is simply that a theoretically 1016 irrelevant variable related to laboratories and their methodological decisions appears to have 1017 a substantial and systematic effect on measured effect size (see also Bergmann et al., 2018) 1018 for a similar conclusion based on meta-analytic data). We hope to undertake future 1019 secondary analyses of our dataset to better understand factors that may have covaried with 1020 methodological choices. Moreove, further large-scale projects that include methodological 1021 contrasts of this type – perhaps with random assignment – may allow us to draw more 1022 specific conclusions about the sources of methodological variability, and their interactions 1023 with phenomenon and participant age. 1024

Another methodological contribution of this project was our investigation of how 1025 different infant-level inclusion criteria affect the magnitude of the obtained effect size. For 1026 our main analysis, we included all infants who completed at least one IDS and one ADS trial. 1027 This is somewhat a departure from the literature using this paradigm, as most participating 1028 labs reported using a stricter inclusion criterion in their own independent work. Our original 1029 meta-analytic effect size was 0.35 when we included all infants with a minimum of two trials, 1030 grew to 0.42 with a minimum of four trials, and 0.48 with a minimum of eight trials. 1031 Moreover, there was substantially more missing data from younger infants in the 1032 eye-tracking paradigm compared with the other methods. While missing data increased 1033 across the length of the experiment, this increase was particularly prevalent for eye tracking. 1034 Setting stricter inclusion criteria necessarily decreases sample size with the same number of 1035 total infants tested, but at the same time stricter criteria appear to lead to more robust 1036 effects in this paradigm. 1037

¹⁰³⁸ Challenges and Limitations

As with any study, the current experiment required specific methodological choices, 1039 several of which influence the generalizability of our results. Two aspects of the 1040 decision-making regarding the stimuli in particular are worth further discussion. The first is 1041 the choice to use North American English (as opposed to, say, the native language or dialect 1042 for each infant group tested). This choice was based on the need to use consistent stimuli 1043 across laboratories to limit cross-lab variation and ensure feasibility of the overall project, 1044 and to use stimuli from a language in which there was robust evidence of a strong IDS 1045 preference effect, both in a native and non-native setting. However, our design necessarily 1046 complicates the interpretability of our findings from laboratories outside of North America. 1047 They confound native-language/dialect effects (infants prefer listening to their native 1048 language) and true cultural variation in IDS preference. Further, there is substantial 1049 diversity in the non-North American English samples that is obscured in our pre-registered 1050 analyses. Together with the previously-mentioned native-language follow-up studies using 1051 the ManyBabies 1 protocol, further analyses of our dataset on specific sub-samples with 1052 sufficient sample size (e.g. French, German, Dutch, British English) will shed additional light 1053 on how the differences between the North American and other infants in the current study 1054 should be interpreted. 1055

The second challenging decision hinged around the elicitation of the IDS stimuli. 1056 Stimuli used in previous IDS preference literature range from scripted speech with no infant 1057 present (e.g., Cooper & Aslin, 1990; Newman & Hussain, 2006), which maximizes 1058 experimental stimulus control, to more naturalistic samples collected from free-play, 1059 unscripted contexts (e.g., Hayashi et al., 2001; Werker et al., 1994), which maximizes 1060 generalizability to real-world contexts. We opted for a relatively naturalistic approach, with 1061 an elicitation protocol using real mothers and their infants centred around concrete objects. 1062 It is likely that this approach may have led to the reduction in the distinctiveness of the 1063

acoustic characteristics of the IDS samples that we observed, and it limited our ability to 1064 fully control the characteristics of the samples. Other aspects of our elicitation approach are 1065 important to keep in mind in interpreting findings such as our developmental effects – 1066 namely the age range of the "target" infants (4-8 months) and the objects-focused nature of 1067 the task (something likely best suited to infants at the older range of our age bins). The 1068 extent to which these age-related characteristics of IDS affect the magnitude of infants' IDS 1069 preference across development merits further inquiry. Further, and as noted above, the use of 1070 multiple speakers in the stimuli may have increased the processing load for infants. 1071

As the first collaboration of its kind, ManyBabies 1 revealed a number of important 1072 challenges in conducting multilab infant collaborations. As any lab that has tested infant 1073 participants knows, data collection is slow and labour intensive. Over a period of 1074 approximately 13 months, 69 labs were able to collect data from 2845 infants. In contrast, 1075 ManyLabs 1, a similar initiative with adults participants (Klein et al., 2014), was able to 1076 collect data from more than 6000 participants tested in 36 labs over just a handful of months. 1077 Moreover, while adults can often be tested in multiple studies in a single session, this option 1078 is very limited for infants. 1079

We expected challenges in implementing a standardized data collection procedure 1080 across infant labs, but the depth of these challenges, and the diversity of methodological 1081 implementation across laboratories, was surprising. Infant laboratories are highly diverse in 1082 both the software and hardware they have available to implement experimental infant testing 1083 methods. We planned flexibility in the specific setup (evetracking, HPP, central fixation) due 1084 to known variability, but despite this several labs were forced to deviate from aspects of the 1085 protocol, for example due to limitations of how stimuli could be presented (e.g., the ability 1086 to implement infant-controlled trial lengths, software settings for repeating trials, etc.). One 1087 important conclusion from our work, as evidenced in the "walk through videos" laboratories 1088 provided to illustrate their protocols (see below), is the extent to which a typical methods 1089

¹⁰⁹⁰ section fails to capture this methodological diversity.

1091 Additional Benefits of Large-Scale Collaboration

While our primary goal was an empirical one, the ManyBabies 1 project had numerous 1092 additional benefits to both individual researchers as well as the field at large. All of the 1093 questionnaires, and how-tos, and stimuli (e.g., attention getters) used in the project are freely 1094 available for re-use in future studies. Each participating lab created a walkthrough video 1095 that showed their lab and study setup. These videos provide an unprecedented peek "behind 1096 the curtain" of other infancy labs, which was previously only possible through visiting labs in 1097 person. Such information could be a particularly helpful resource for investigators setting up 1098 an infant lab for the first time. It also provides a unique dataset whereby the field of infant 1099 research can begin to understand the variety of lab setups and study implementations. 1100

This large-scale collaborative effort also had broader benefits for the field. It created a strong collaborative network of infancy researchers. Informal "ManyBabies" gatherings are now organized at developmental conferences, enabling researchers who have previously collaborated only virtually to meet in person. It also was many researchers' introduction to open and cumulative science practices and tools, such as pre-registration and the Open Science Framework.

Finally, ManyBabies 1 has launched several "knock-on" projects. For example, ManyBabies Bilingual (Byers-Heinlein et al., accepted pending data collection) is comparing bilingual infants' preference for infant directed speech with our results from monolinguals. Other projects will examine the test-retest reliability of infants' IDS preference, examine whether IDS preference predicts vocabulary size at 18 and 24 months (Soderstrom et al., accepted pending data collection), and test whether lab-specific variables affect infant performance and attrition. We believe that these additional benefits are not unique to infancy research, and that other scientific communities embarking on large-scalecollaborative projects will garner similar benefits.

1116 Conclusion

Replication research can go far beyond simply asking whether an effect is present: it 1117 can allow for an assessment of how an effect varies and how it develops. We observed a 1118 robust and statistically significant preference for IDS over ADS, confirming previous 1119 observations in the literature. Yet the value of our experiment lies not purely in this binary 1120 result – or even in the quantitative estimate of the overall magnitude of the IDS preference – 1121 but in the further theoretical and methodological opportunities that the data afford. By 1122 measuring the relationship of IDS preferences to age and language community, this 1123 experiment provides a starting point for developing a more nuanced theory of how IDS 1124 preferences relate to children's language experiences. Further, by revealing the substantial 1125 contributions of methodological decision-making to effect size, our study points the way 1126 towards developing best-practices templates in further infancy work of this kind. In sum, we 1127 hope our work here illustrates the power of large-scale collaboration for the study of 1128 developmental variation and change. 1129

1170

1167

Disclosures

¹¹⁷¹ **Preregistration**

¹¹⁷² Our manuscript was reviewed prior to data collection; in addition, we registered our ¹¹⁷³ instructions and materials prior to data collection (https://osf.io/gf7vh/).

1174 Data, materials, and online resources

All materials, data, and analytic code are available at https://osf.io/re95x/; the specific code and data required to render this document are available at https://osf.io/zaewn/.

1177 Reporting

¹¹⁷⁸ We report how we determined our sample size, all data exclusions, all manipulations, ¹¹⁷⁹ and all measures in the study.

1180 Ethical approval

All labs collected data under their own independent ethical approval via the appropriate governing body for their institution. Central data analyses used exclusively de-identified data. Identifiable video recordings of individual infant participants were coded and archived locally at each lab; where IRB protocols permitted, video recordings were also uploaded to Databrary, a central controlled-access database accessible to other researchers (Databrary, n.d.).
