Abstract

Invasive aquatic plants constitute a great problem in many freshwater systems. Although many studies have addressed the potential threats of invasion by exotic species in aquatic ecosystems, few studies have considered the interactions (competition, facilitation, coexistence) between exotic aquatic plants of similar growth form in invaded communities. Our aim was to investigate experimentally the effect of density in monocultures and the effect of neighbour identity and plant density on a focal species in mixed cultures. We used *Elodea canadensis*, *Egeria densa* and *Lagarosiphon major* as model species and conducted two experiments, one in a monoculture and another in a mixed culture following an additive design. Individuals were planted in pots with several treatments based on the identity and density of neighbour species. Our results demonstrated that the development of an invasive submerged plant could be influenced either positively (facilitation) or negatively (competition or inhibition) by the presence of more than one neighbour species of different densities. An increase in density significantly stimulated competition intensity, although the effect of density on the performance of the invader also depended on neighbour identity. A facilitative effect of *E. canadensis* on the apical growth of *E. densa* was established. However, despite these results, the competitive outcome also depended on other environmental factors (e.g. underwater radiation) and not on plant density and neighbour identity alone.

Keywords: non-native species, clonal plants, morphological traits, Hydrocharitaceae

Introduction

Invasive aquatic plants constitute a major problem in many freshwater systems (Dugdale et al. 2012), being able to affect both biodiversity and ecosystem functioning (Clayton and Edwards 2006). Although many studies have addressed the potential threats of invasion of aquatic ecosystems by exotic species (Spencer and Rejmanek 1989; Rahel and Olden 2008), few studies have considered the interactions (competition, facilitation, coexistence) between exotic aquatic plants with a similar growth form in invaded communities (Barrat-Segretain and Elger 2004; Mony et al. 2007; Silveira et al. 2018). There is some evidence that positive interactions (facilitation) can occur (Thomaz et al. 2012). Exotic species may facilitate the successful establishment of other exotic species by creating suitable environmental conditions (e.g. increasing nitrogen availability). For example, Santos et al. (2011) found that invasion by *Myriophyllum spicatum* facilitated the spread of *Egeria densa* in California.

Conversely, competition is widely regarded as one of the most important mechanisms of species invasion and has been shown to play a large role in macrophyte communities (Moen and Cohen 1989; Mc Creary 1991). This negative interaction is expected to occur mostly between species with a similar growth form and between closely related species, assuming that closely related species share similar niches and traits (Violle et al. 2011). However, only a few studies have focused on the competition between aquatic plant species with such characteristics (James et al. 1999; Barrat-Segretain and Elger 2004; Mony et al. 2007; Sousa et al. 2010; Gérard et al. 2014). The occurrence of invasive plant species in high densities may generate competition for resources (Ren and Zhang 2009), which can inhibit the growth of other plants (Wang et al. 2008). Thus, plant density manipulation is one of the main tools to study competition between plant species, as it can modify plant growth by influencing plant nutrient uptake (Creed et al. 1997; Xie et al. 2006).

Elodea canadensis Michaux, *Egeria densa* Planchon, and *Lagarosiphon major* Rid. Moss ex Wager are considered to be the most troublesome submersed species in the world. They belong to the Hydrocharitaceae family and have an elodeid life form. The two submersed species *E. densa* and *L. major* form dense monospecific mats in their introduced range, whereas *E. canadensis* can co-exist with native submersed plants. However, *E. densa* and *L. major* can co-occur in freshwater ecosystems, for example, they co-exist in Lake Lacanau, a shallow lake located in the southwest of France (Ribaudou et al. 2018). The three species are dioecious clonal plants that mainly disperse vegetatively in their natural habitats, and even small fragments of all three species can establish and develop into new

macrophyte beds (Howard-Williams 1994; Riis et al. 2012). Native from North America, only female plants of *E. canadensis* were introduced outside their native range (Cook and Urmi-König 1985). Similarly to *E. canadensis*, *E. densa* and *L. major*, coming from South-America and South-Africa respectively, were introduced into France, from where they have become widely distributed in many European countries (James et al. 1999; Cook and Urmi-König 1984; McKee et al. 2002; Silveira et al. 2018). Despite their similarities, the distinctive nature of each genus is demonstrated by the fact that *Elodea* is unable to hybridize with *Egeria* (Cook and Urmi-König 1985). Les et al. (2006) showed that the genus *Lagarosiphon* is not closely related to the genera *Elodea* and *Egeria*, but they recognized a clade containing *Egeria*, *Elodea* and *Lagarosiphon* at the rank of subfamily. Our aim was to investigate experimentally the effect of density in monospecific cultures and the effect of neighbour identity and plant density on the growth of focal species in mixed cultures during the early growth stage of these invaders. We used *E. canadensis*, *E. densa* and *L. major* as model species to test the following hypotheses: i) the performance of the invaders is reduced at high density both in monocultures and in mixtures; and ii) the presence of plants with a similar growth form may increase competition in mixed cultures.

Materials and methods

Material sampling

More than 280 fragments of each species (*E. canadensis*, *E. densa* and *L. major*) were collected randomly in the spring from three different ponds located in Brittany in western France (Table 1). Ramets, hereafter called “Plants”, were derived from a single clone either of *E. canadensis*, *E. densa* or *L. major*.

Water was sampled close to the macrophyte beds where the plants were collected. Samples were kept refrigerated during transport to the laboratory and chemical analyses were carried out within 24h after sampling. Plants were collected from sites with alkaline water and a mean temperature of 15.3°C, with low oxygen content (mean value $O_2 = 31.5 \%$) and moderate conductivity (mean value conductivity = $308 \mu S \text{ cm}^{-1}$). All species grew in eutrophic waters (see Supplementary Material S1). In the laboratory, the apical shoots of *E. canadensis* (*Ec*), *E. densa* (*Ed*) and *L. major* (*Lm*) were washed to remove invertebrates, algae and debris. Plants were acclimatized for one week at ambient temperature (close to 20°C) in tap water which was slightly basic with a moderate nutrient

concentration (mean annual values according to French Water Agency data: conductivity = 400 $\mu\text{S cm}^{-1}$; pH= 8.10; $[\text{NO}_3^- \text{N}] = 1.44 \text{ mg L}^{-1}$; $[\text{NH}_4^+ \text{N}] = 0.03 \text{ mg L}^{-1}$; $[\text{PO}_4^{3-} \text{P}] = 0.05 \text{ mg L}^{-1}$).

Experimental design

Two experiments were conducted. In the first experiment, plants were cultivated as monocultures with two density levels. In the second experiment, the effects of both neighbour identity and density were tested in mixed cultures. The experiments were performed simultaneously.

Monoculture experiment

Each pot (L x W x H): 8cm x 8cm x 15cm was filled with 2 cm of substrate (loam) and 3cm of sand and tap water. Fertile fine-grained sediments, such as loam, contain high levels of organic matter with anaerobic conditions and are suitable for the growth of *L. major* (Martin and Coetzee 2014) and other macrophyte species. Individuals of each species were prepared by taking an apical shoot of 7 cm length, without buds or lateral stems. These ramets were planted 2 cm apart in the centre of each pot. The distance between ramets was the same for high (4 individuals) and low (2 individuals) densities. Pots were randomly distributed in the growth chamber (photoperiod: 12 h of light/12 h of darkness; light intensity 50% corresponding to 300-500 $\mu\text{mol m}^{-2} \text{ s}^{-1}$) and at a temperature of 19°C. Light intensity and temperature were chosen according to the growth optimum of the three invasive species in spring (Riis et al. 2012; Silveira and Thiébaud 2017).

After four weeks, four morphological traits were measured: length of the stem, leaf area, number of lateral shoots and number of roots. To measure leaf area, the surface of one leaf taken at 3 cm from each plant apex was scanned and thereafter measured using Scion Image software. Relative Growth Rate (RGR) and Leaf Area Growth Rate (LAGR) of the macrophytes were calculated using the following equation: $\text{RGR} = (\ln L_2 - \ln L_1) / (T_2 - T_1)$, where L_1 and L_2 refer to plant length at times T_1 and T_2 (Barrat-Segretain and Elger 2004). LAGR was calculated using the same equation, where L_1 and L_2 refer to leaf area surface. LAGR was considered as a proxy of plant Photosynthetic ability (Weraduwaage et al. 2015). This experiment also served as the control for calculating Relative Neighbour Effect (RNE) in the mixed culture experiment.

Mixed culture experiment

The same experimental design was applied to the mixed culture experiment. The effects of the experimental conditions were tested by combining different ratios of *E. densa*, *E. canadensis* and *L. major* individuals for a total density of two or four individuals per pot. Individuals were planted 2 cm

apart in the centre of each pot. The distance between ramets was the same for high and low densities. Experimental conditions consisted of planting individuals of *E. canadensis*, *E. densa* and *L. major* to give two plant densities (2 or 4 individuals) and using different species ratios (i.e. Mid-ratio = 1/1 or 2/2; High-ratio = 3/1 and Low-ratio = 1/3). The first number is the focal species and the second number the neighbour. The treatments consisted of pots (containing two or four individuals), with the following ratios: Mid-ratio pots: pots including two individuals, one focal species and one neighbour species - 1/1, or pots including four individuals, two focal species and two neighbour species - 2/2. These treatments are shown in Figures 2 and 3 as: Mid-ratio (1) = 1/1; and Mid-ratio (2) = 2/2. High-ratio pots: including four individuals with a ratio of three individuals of the focal species to one neighbour species - 3/1. Low-ratio pots: including four individuals with a ratio of one individual of the focal species to three neighbour species - 1/3. The combinations of focal species and neighbours were: focal *E. canadensis* with *L. major* and *E. densa* as neighbour species; focal *E. densa* with *L. major* and *E. canadensis* as neighbour species; and focal species *L. major* with *E. densa* and *E. canadensis* as neighbour species. Each treatment had five replicates. The pots were placed randomly in the growth chamber under the same conditions as the monoculture experiment.

At the end of the experiment, the same four morphological traits were measured: Relative Growth Rate (RGR), Leaf Area Growth Rate (LAGR), number of lateral shoots and number of roots. We also measured competition intensity. The relative competitive index (RCI) which compares the performance of a target plant grown in monoculture or mixed with neighbours, is one of the most widely used indices to quantify competition between plant species (Wilson 2007), whereas the Relative Neighbour Effect (RNE, Markham and Chanway 1996) is a calculation of the neighbour effect relative to the plant with the greatest performance. The RNE is an improvement of the RCI index as it compares the performance of plants growing in monoculture and in the presence of neighbour species (Weigelt and Jolliffe 2003). The RNE index is symmetric around zero and constrained between +1 (competition) and -1 (facilitation), so it can be used to estimate facilitation interactions. We calculated the RNE index for each trait as follows:

$$RNE = (P_{control} - P_{mixture})/x$$

where $P_{control}$ is the trait of the target species planted in monoculture (= control) and $P_{mixture}$ is the trait of the same target species in the presence of a neighbour species. The term x depends on which value of P is greater. If $P_{control} > P_{mixture}$, then $x = P_{control}$; however, if $P_{mixture} > P_{control}$, then $x = P_{mixture}$. The

traits used were: RGR, number of shoots, number of roots and leaf area of each individual planted in monoculture or mixed culture.

Statistical analyses

To test for the effects of density and species identity on the morphological traits of the plant species in the monoculture experiment, we performed a two-way ANOVA. We applied Tukey's HSD test to test for pairwise differences between treatments. In the mixed culture experiment, to test the effect of neighbour identity, plant density and its interactions on the RNE of each trait and on each morphological trait, we used a two-way ANOVA. Permutation tests avoid the assumption of normality (Anderson 2001). For this reason, the two-way ANOVA of both treatments (e.g. monoculture and mixed culture) was performed by permutation ($\alpha = 0.05$; 9999 permutations). These analyses were done using software R Development Core Team (R Core Team 2016). The effects of neighbour identity, plant density and their interactions on the RNE of each trait and on each morphological trait were tested using a "post hoc" Tukey test. These analyses and graphics were performed using Statistica TM 10.0.

Results

Effect of plant density in monoculture

We found greater RGR and a higher number of shoots in *E. canadensis* than in *E. densa* and *L. major* (Table 1; Fig. 1 a and c). The LAGR did not differ between species (Table 1, Fig.1b). Our test indicated a significant difference in the production of roots among species: *E. densa* produced a significantly lower number of roots compared to the other species at both low and high densities (Table 1; Fig. 1 d). The LAGR was lower for *L. major* at high density and for *E. canadensis* at low density (Table 1, Fig.1b).

Different small letters above columns are used to indicate a significant difference between species and densities.

Effect of density and neighbour identity on RNE and morphological traits

The calculation of the RNE index for each morphological trait indicated that there was competition or facilitation between the three species depending on the different treatments (Fig. 2.A-M). However, at Mid-ratio (1), length of *E. densa* was slightly facilitated by the presence of *E. canadensis* (Fig. 2.B - treatment Mid-ratio (1)). Strong competition was established at high density for the production of lateral shoots of *E. canadensis* when it was outnumbered by *L. major* (Table 2, Fig. 2.D - treatment Low-ratio). Higher competition intensities were shown for the formation of the number of roots of *E. canadensis* when the neighbour species was mainly *L. major* and *E. densa* (Fig. 3.G - treatment Mid-ratio (2), Low-ratio and High-ratio), however root formation was stimulated in the presence *L. major* in the Mid-ratio (1) treatment. Leaf area growth of all species, RGR of *E. canadensis* and *L. major*, and the production of lateral shoots by *E. densa* and *L. major* were not impacted by the interactions between neighbour identity and plant density (Table 2; Fig. 2).

Figure 2: Means and standard errors of the RNE of each morphological trait (Relative Growth Rate = RGR), lateral shoot number, root number and leaf area growth rate = LAGR) of *E. canadensis*, *E. densa* and *L. major* at two plant densities and different ratios (Mid-ratio (1) = 1/1; Mid-ratio (2) = 2/2; Low-ratio = 1/3 and High-ratio = 3/1). The first number is the focal species and the second number the neighbour. Empty Circle: *E. canadensis*, Empty Square: *E. densa*, Black Triangle: *L. major*. Different small letters above columns are used to indicate a significant difference between species and densities.

Our results showed no effect of plant density and neighbour species on the RGR of *L. major* (Table 3, Fig. 3C), on the number of lateral shoots of *E. densa* and *L. major* (Table 3, Fig. 3, E, F) or on the LAGR of *E. canadensis*, *E. densa* and *L. major* (Table 3, Fig. 3 J, L, M).

However, they demonstrated significant effects of both plant density and neighbour species on the RGR and the number of lateral shoots of *E. canadensis* (Table 3, Fig. 3A, D). *E. canadensis* showed a lower RGR in the presence of *L. major* than in the presence of *E. densa* in the High-ratio treatment, whereas the presence of *E. densa* induced a reduction of the production of lateral shoots in the Mid-ratio (2) and Low-ratio (Fig. 3A, D) treatments. *E. canadensis* exhibited lower root production in the presence of *L. major* at high density (Fig. 3G - treatment High-ratio). The RGR of *E. densa*

depended on plant density and neighbour identity (Table 3, Fig. 3B). *E. canadensis* stimulated the RGR of *E. densa* (Treatment Mid-ratio (1), Fig. 3B). *L. major* had high root production whether the neighbour was *E. canadensis* or *E. densa* in the Mid-ratio (1) treatment (Fig. 3I).

Discussion

Effect of density on morphological traits of invaders in monoculture and in mixtures.

Our results demonstrated that the performance of invasive submerged plants was density-dependent and that it could be influenced positively (facilitation) or negatively (competition) by the identity of neighbour species. Indeed, in high density, the LAGR of *L. major* and the root number of *E. densa* were reduced. A high density increased competition for resources by limiting light interception and nutrient uptake, and consequently reduced leaf growth and root production. However,

leaf area growth of *E. canadensis* was stimulated at high density in monoculture, suggesting an investment in photosynthetic capacity as a strategy to overcompensate for stress. No intraspecific competition for initial growth (apical and lateral growth) was seen in monocultures independently of treatments with low or high densities. The latter results were surprising, because two individuals of the same species have exactly the same ecological requirements, and competition may occur rapidly when one factor is limited in the environment (Barrat-Segretain and Elger 2004). The short period of the experiment may not have been long enough to induce nutrient stress and this could explain the weak competitiveness between individuals, as longer experiments have shown strong intraspecific competition effects and niche differentiation (Barrat-Segretain and Elger 2004; Stiers et al. 2011). However, other studies have reported equivalent or stronger interspecific effects (Aguiar et al. 2001; Mony et al. 2007; Spencer and Rejmánek 2010; Yu et al. 2018). For example, Yu et al. (2018) found higher interspecific competition than intraspecific competition for *E. densa*. Our results also showed an interspecific competition for root production between the three invaders. Moreover, an increase in density significantly stimulated competition intensity, although the effect of density on the performance of the invader also depended on neighbour identity. Our results in mixed culture were broadly similar to the findings in monoculture, demonstrating that a high density had a strong impact on the interspecific competition for all three species. From this, we can infer that the results obtained in monoculture and mixed cultures are probably due to the fact that the plants are morphologically similar, that the mechanisms driving intraspecific and interspecific competition are very similar for these submerged plants and that the performance of invaders was density-dependent. Thus, our results partially corroborate our first hypothesis for *E. canadensis*, *E. densa* and *L. major*.

The presence of plants with similar growth form may increase competition in mixed cultures.

Although the morphological development of *E. canadensis* was mainly influenced by plant density, the numbers of lateral shoots (= lateral growth) and roots of this species were slightly related to the identity of the neighbour species. The lowest apical growth and root and lateral shoot production of *E. canadensis* when this species grew with *L. major* could be consequences of competition for nutrient uptake and space between *E. canadensis* and *L. major*. It is well known that the presence of plants with similar growth form and architecture can negatively affect nutrient concentrations in the sediment and solar radiation available for the plant community which may increase competition, thus

inhibiting plant growth. Other authors have demonstrated similar results, for example, Riis et al. (2012) also showed that *L. major* and *E. canadensis* differ in their branching and stem length under similar experimental conditions (i.e. at temperatures close to 20°C and 50% light). Under these conditions, *E. canadensis* is the most competitive species regarding morphological characteristics at 20 °C especially due to its high degree of branching (Riis et al. 2012), on the other hand, *L. major* has a highest stem length. Our results showed low competition intensity for branching and root production at high intensities. Surprisingly, the response of *E. canadensis* differed in the presence of *E. densa* and *L. major*. Furthermore, a facilitative effect of *E. canadensis* on the RGR (apical growth) of *E. densa* was established. The presence of *E. canadensis* stimulated the RGR of *E. densa* (RGR in the presence of Ec = 0.028 ± 0.004 cm per day, in presence of Lm = 0.015 ± 0.009 cm per day). Conversely, the presence of *E. densa* did not influence the RGR of *E. canadensis*. Thus, interactions between *E. canadensis* and *E. densa* were distinctly asymmetrical. Plant density did not influence *L. major* traits, except for root production in mixtures, indicating that species coexistence is favoured instead of competitive exclusion (Stiers et al. 2011). Thus our hypothesis, that the presence of plants with similar growth form may increase competition in mixed cultures was partially validated.

Neighbour identity had no impact on *L. major*. The RGR of *L. major* at high density was on average 0.014 cm per day in the presence of *E. canadensis*, whereas the RGR of *E. canadensis* was around 0.030 cm per day at high density in mixtures. Moreover, the leaf area growth of *L. major*, a proxy for photosynthetic ability, was not affected by density or neighbour identity. The apical growth ability of *E. canadensis* may enable it to shade out neighbouring species and outpace the establishment of other species such as *L. major*. These results are not consistent with the literature. For example *L. major* may be successful in out-competing *Elodea* spp. as a result of its ability to photosynthesize and consequently grow, particularly under very stressful conditions of high pH and low free CO₂, perhaps through more efficient bicarbonate utilization than the other species (James et al. 1999). Competition intensity for root production of *L. major* increased slightly with density, whatever the neighbour species. Therefore the outcome of competition between species of the same family, having similar architecture and competition ability, is not the same. For example, Mony et al. (2007) showed that *H. verticillata* may out-compete *E. densa* in many situations and Hofstra et al. (1999) established that the growth of *H. verticillata* appeared to be impeded by the dense *E. densa* canopy and that under particular environmental conditions *E. canadensis* may still coexist with *H. verticillata* or even

dominate some habitats. Our results are original because they also suggested that the interactions between invaders depended on the identity of the neighbour in mixed cultures.

Our experimental study indicated that *E. canadensis* was characterized by the highest RGR and number of roots and lateral shoots in both treatments (monoculture and mixed culture), suggesting that *E. canadensis* is a stronger competitor than *E. densa* and *L. major* (Riis et al. 2012; Silveira and Thiébaud 2017). Furthermore, Redekop et al (2016) demonstrated that *E. canadensis* shows a higher dispersal capacity via fragmentation than *E. densa* and *L. major*. This capacity increases its potential invasiveness. However, the highest dispersal ability of *E. canadensis* does not explain its low abundance in the field, where it has been shown that *E. canadensis* was displaced by *Elodea nuttallii* and *E. nuttallii* by *L. major* (James et al. 2006). Furthermore, *E. canadensis* was not considered as an aggressive species in Polish lakes (Kolada and Kutyla 2016). Similarly, a clear difference was obtained between experimental conditions and field observations in the study of Hofstra et al. (1999). These authors established that *H. verticillata*, a world-wide invasive species belonging to the Hydrocharitaceae family, had little apparent impact on the competitor species biomass (*E. densa*, *L. major*, *E. canadensis*), whereas *H. verticillata* out-competed these species in Lakes in New Zealand.

This study experimentally demonstrated that despite the fact that the three invasive species were morphologically similar, the positive (facilitation) or negative (competition) effects of density on performance of each species depend on the identity of the neighbour species and on the degree of density. This finding implies that the presence of one invasive species (focal species) can be inhibited or facilitated by the introduction of other exotic species (neighbour species). Our study demonstrated that the species least affected by neighbour species was the invasive *L. major*, whereas *E. canadensis* and *E. densa*, were affected by the presence of other neighbour species. These results suggest that *L. major* can be considered as the most aggressive species.

However, we emphasize that these observations were recorded in the early stages of fragment regeneration, and whether they also pertain to later life stages is a matter for further investigation.

Acknowledgements

The authors thank Dra. Vanessa C. Harthman (Universidade Estadual de Maringá) for fruitful discussion, Msc. Dieson André by help with quality of the figures and the two anonymous reviewers for suggestions that have improved our manuscript a lot. We also thank Bertrand Coupé and Marc Hervé for their help in the field and Nathalie Josselin-Le Bris for assistance with water analyses. M.J.

Silveira is grateful to the National Council for Scientific and Technological Development (CNPq), for providing a Post Doctorate scholarship and Rennes Metropole.

Figure captions

Figure 1: Means and standard errors of each morphological trait (Relative growth rate = RGR, lateral shoot number, root number and Leaf area growth rate = LAGR) of *E. canadensis*, *E. densa* and *L. major* in monocultures at two plant densities. Empty symbols = low density; Black symbols = high density. Circle: *E. canadensis*, Square: *E. densa*, Triangle: *L. major*. Different small letters above columns are used to indicate a significant difference between species and densities.

Figure 2: Means and standard errors of the RNE of each morphological trait (Relative Growth Rate = RGR), lateral shoot number, root number and leaf area growth rate = LAGR) of *E. canadensis*, *E. densa* and *L. major* at two plant densities and different ratios (Mid-ratio (1) = 1/1; Mid-ratio (2) = 2/2; Low-ratio = 1/3 and High-ratio = 3/1). The first number is the focal species and the second number the neighbour. Empty Circle: *E. canadensis*, Empty Square: *E. densa*, Black Triangle: *L. major*. Different small letters above columns are used to indicate a significant difference between species and densities.

Figure 3: Means and standard errors of each morphological trait (relative Growth Rate = RGR), lateral shoot number, root number and leaf area growth rate = LAGR) of *E. canadensis*, *E. densa* and *L. major* at two plant densities and different ratios (Mid-ratio (1) = 1/1; Mid-ratio (2) = 2/2; Low-ratio = 1/3 and High-ratio = 3/1). The first number is the focal species and the second number the neighbour. Empty Circle: *E. canadensis*, Empty Square: *E. densa*, Black Triangle: *L. major*. Different small letters above columns are used to indicate a significant difference between species and densities.
