<sup>∅</sup>Drs. Donal and Hubert contributed equally to this manuscript.

Although previous studies have suggested that the analysis of mechanical dyssynchrony can improve prediction of response to cardiac resynchronization therapy (CRT), current guidelines still neglect the value of left ventricular (LV) mechanical dyssynchrony assessed by imaging techniques, particularly echocardiography. Recently, machine-learning methods have offered new opportunities to analyze complex features in cardiology (1). We hypothesized that a multiparametric evaluation, based on the combination of electrocardiographic and echocardiographic parameters, analyzed by an automated machine-learning system based on the random forest (RF) method, could enhance the appraisal of the likelihood of reverse remodeling and prognosis of favorable clinical evolution after CRT.

A total of 154 heart failure patients, with an ejection fraction <35% and QRS duration >120 ms, who had a CRT device implanted in Rennes University Hospital between 2010 and 2017, were retrospectively studied. A total of 109 patients (71%) were responders, defined by a decrease in LV end-systolic volume >15% at 6-month follow-up. The mean age of the overall population was  $65 \pm 10$  years, there were 103 (67%) men. Mean QRS width and LV ejection fraction were  $164 \pm 18$  ms and  $28 \pm 7\%$ , respectively. Ischemic cardiomyopathy was identified in 45 (29%) patients. All patients had a complete baseline echocardiography before implantation (Ve9, Ve95, GE Healthcare, Horten, Norway) and at 6-month followup, with offline parameters measurement according to the current guidelines by a certified senior echocardiographer. Custom-made signal processing methods, developed with MATLAB software (MathWorks Inc.), were used to analyze automatically the 4-chamber longitudinal strain, providing 60 different features, particularly dyssynchrony parameters and integrals of regional longitudinal strain signals, as described in Bernard et al. (2). QRS duration was also included in the analysis as an additional feature. Electrocardiogram (ECG) and echocardiographic parameters were selected first, based on a filtering cutoff of Pearson's coefficient >0.8. The R) method was then applied to analyze the relative importance of the remaining features and to obtain the 6 most significant features. A final RF method was applied to the 6 selected features, with the objective of predicting response to CRT. A Monte Carlo crossvalidation method with 30 runs was applied, using, in each run, different random sets of 70% of patients for training and 30% for testing.

Results showed a mean area under the curve (AUC) of 0.804 with a standard deviation of 0.03 (0.77 to 0.94) (Figure 1). In contrast, the best classification performance for a single variable was obtained with a strain-based measurement of myocardial wasted energy of the septal wall, with an AUC of 0.686, followed by QRS duration with an AUC of 0.668.

Our study demonstrates that the machine-learning approaches may be useful to improve the estimation of good candidates for CRT. Linear models are useful to find variables that are significantly different between groups, but these variables are not necessarily associated with outcomes. Through the iterative creation of models from a significant number of variables, machine learning allows the identification of the model that best fits the primitive clinical question. It optimally combines complementary information on the patients' susceptibility to respond favorably to a predefined treatment (3,4). Combing multiple data might allow a move to "precision medicine" (5). Moreover, this study underlines the complementary value of LV dyssynchrony parameters with respect to standard ECG analysis and proposes a method to estimate CRT response by combining a limited number of sensitive ECG and echocardiography parameters. Finally, this approach demonstrated that a fast semiautomated echocardiographic method, based only on a longitudinal strain curves that is strongly reproducible even for novice readers, could provide useful information to better select CRT candidates. Although our population is limited, the Monte Carlo cross-validation method is robust through many tests using subgroups for learning and a subgroup for testing.

When analyzed in a multiparametric approach using machine-learning algorithms, a combination of echo-based parameters of LV dyssynchrony and QRS duration helped to improve the prediction of the response to CRT.
